

Hydrodynamics of Stirred Tank using Radioactive Particle Tracking (RPT) Technique and CFD

Submitted in partial fulfilment of the requirements for the award of the degree of

DOCTOR OF PHILOSOPHY

in

CHEMICAL ENGINEERING

by

PATIL HARSHAL SOMNATH

Roll No: 715068

Under the Supervision of

Dr. A VENU VINOD

Professor

Department of Chemical Engineering

and

Dr. AJEY KUMAR PATEL

Assistant Professor

Department of Civil Engineering

**DEPARTMENT OF CHEMICAL ENGINEERING
NATIONAL INSTITUTE OF TECHNOLOGY WARANGAL
TELANGANA – 506004, INDIA.**

September 2020

NATIONAL INSTITUTE OF TECHNOLOGY
Warangal – 506004, Telangana, INDIA.

CERTIFICATE

This is to certify that the thesis entitled “**Hydrodynamics of Stirred Tank using Radioactive Particle Tracking (RPT) Technique and CFD**” being submitted by Mr. **Patil Harshal Somnath** for the award of the degree of Doctor of Philosophy (Ph.D) in Chemical Engineering to the National Institute of Technology, Warangal, India is a record of the bonafide research work carried out by him under our supervision. The thesis has fulfilled the requirements according to the regulations of this Institute and in our opinion has reached the standards for submission. The results embodied in the thesis have not been submitted to any other University or Institute for the award of any degree or diploma.

Date: 01/09/2020

Dr. A. Venu Vinod
Thesis Supervisor
Professor
Department of Chemical Engineering
National Institute of Technology, Warangal,
India.

Dr. Ajey Kumar Patel
Thesis Supervisor
Assistant Professor
Department of Civil Engineering
National Institute of Technology, Warangal,
India.

DECLARATION

This is to certify that the work presented in the thesis entitled **“Hydrodynamics of Stirred Tank using Radioactive Particle Tracking (RPT) Technique and CFD”** is a bonafide work done by me under the supervision of Dr. A. Venu Vinod and Dr. Ajey Kumar Patel and it was not submitted elsewhere for award of any degree.

I declare that this written submission represents my ideas in my own words and where others' ideas or words have been included, I have adequately cited and referenced the original source. I also declare that I have adhered to all principles of academic honesty and integrity and have not misrepresented or fabricated or falsified any idea/data/fact/source in my submission.

I understand that any violation of the above will be a cause for disciplinary action by the Institute and can also evoke penal action from the sources which have thus not been properly cited or from whom proper permission has not been taken when needed.

PATIL HARSHAL SOMNATH

Roll No.715068

ACKNOWLEDGMENTS

First and foremost I would like to thank my supervisors **Prof. A. Venu Vinod** and **Dr. Ajey Kumar Patel** for their disciplined, patient guidance, timely appreciation, extraordinary support enormous enlightening discussion with constructive criticism, inspiring, enticing pieces of advises and sustain inputs during the research work and preparation of thesis. Their guidance is a great learning experience to me throughout my stay at National Institute of Technology Warangal, by strengthening me all the time. I owe a lot to them for their positive encouragement and guidance.

I wish to sincerely thank university authorities, **Prof. N.V. Ramana Rao**, Director, National Institute of Technology, Warangal and other officials who gave me an opportunity to carry out research work.

I also sincerely thank **Prof. Shirish H. Sonawane**, Head, Chemical Engineering Department, National Institute of Technology, Warangal for his continuous support towards carrying out research work.

I wish to express my sincere thanks and gratitude to my doctoral scrutiny committee (DSC) members **Dr. S. Srinath**, **Dr. S. Vidya Sagar**, Department of Chemical Engineering and **Prof. K. V. Jayakumar**, Department of Civil Engineering, National Institute of Technology Warangal, for their kind help, encouragement and valuable suggestions for successful completion of research work.

I would like to extend my thanks to all the faculty members in Department of Chemical Engineering for their valuable suggestions and encouragement.

I take this opportunity to sincerely acknowledge the **Board of Research in Nuclear Science (BRNS)** and **Bhabha Atomic Research Center (BARC), Government of India** for providing the financial assistance and radioactive source to conduct research work at NITW.

I would like to express my sincere thanks to **Dr. Harish J. Pant, Scientist, Bhabha Atomic Research Center (BARC), Government of India** for helping in provision of a radioactive source to conduct research work at NITW. Also, I would like to thanks **Dr. Rajesh Kumar Upadhyay, Associate Professor, IIT BHU**, for providing training on RPT data processing.

I am extremely thankful to Marathi family in NIT Warangal **Dr. Vinay Rangari, Dr. Uday Bagale, Dr. Prashant Suryawanshi, Dr. Abhay Lingayat, Mr. Gajanan Suryawanshi, Mr.**

Roshan Bodile, Mr. Ganesh Gawale, Mr. Upendra Maurya, Mr. Swapnil Adsul, Mr. Avinash Borgaonkar, Mr. Vikas Hakke, Mr. Kishor Ingle, Mr. Sandip Khobragade, Mrs. Vividha Landage, Mrs. Shital Potdar and my dear friends *Mr. Devrajan K., Mr. Yashwant Gowda, Mr. Abdullah Sheikh, Mr. Sukhesh*, for their companionship, many fruitful conversations, help, and quality time spent together throughout my stay at NIT Warangal.

Last but not least, I would like to express my deepest thanks to family members *Dr. Somnath Patil* (Father), *Surekha* (Mother), *Yogesh* (Brother) and *Nayana* (Sister in law) for their understanding, patience, continuous support and heartiest love.

PATIL HARSHAL SOMNATH

Abstract

Stirred tank reactors are widely used in various chemical process and its allied industries to enhance the rate of heat and mass transfer. The rotating impellers in stirred tanks generate the highly turbulent and complex three dimensional flow structure. In present work, radiation based non-invasive Radioactive Particle Tracking (RPT) technique was used and a steady state computational fluid dynamics (CFD) model was developed to study complex flow structures in a stirred tank agitated by Rushton turbine (RT).

In the calibration measurement of RPT technique, the effect of fluid motion on radiation intensity was addressed by analysis of variance (ANOVA) technique. Through the ANOVA analysis it was found that fluid motion has no effect on radiation intensity. RPT correctly shown the radial discharge stream coming out from impeller tip. RPT accurately measured the mean radial, tangential and axial velocities and compared well with established Laser Doppler Anemometry (LDA) technique data.

A steady state CFD model was developed for a standard configured stirred tank. Initially, variants of the $k-\varepsilon$ turbulence models such as standard, realizable, renormalized group (RNG) were tested. Among them standard $k-\varepsilon$ model has given better prediction of mean velocities in comparison with realizable and RNG $k-\varepsilon$ models. Further, the optimal dimensions of inner-rotating fluid zone for multiple reference frame (MRF) technique in CFD modelling of stirred tank were determined. In this study, a series of CFD simulations were performed at various dimensions of inner-rotating fluid zones and the optimal zone dimensions were considered when the results for mean velocities were found to be in good agreement with literature data. The efficiency of CFD model with optimized inner-rotating fluid zone was validated by comparing the prediction of mean velocities, power number at various Reynolds number, radial pumping number, classical flow pattern of double re-circulation loops and turbulence parameters with the RPT and the literature data.

The effect of impeller clearance (from bottom of the tank) on flow hydrodynamics in RT stirred tank was investigated, as it has paramount importance in various applications. A series of CFD simulations were conducted for the clearance ranging from $C/T = 0.15$ to 0.85 . The mean and turbulence flow fields from the stirred reactor configuration having RT impeller at standard as well as lower clearances were validated with the experimental results available in the literature. A critical clearance of $C/T = 0.78$ and 0.18 were determined at which the standard double re-

circulation loop flow pattern was transformed into single re-circulation loop with more than 30% and 44% reduction in the power number as well as radial pumping number respectively. Thus, double re-circulation loop exists in the range of $0.19 \leq C/T \leq 0.77$ and single re-circulation loop occurs in the range of $C/T \leq 0.18$ and $C/T \geq 0.78$. Therefore, the radial flow pattern associated with the standard RT clearance changed into axial flow pattern. The higher clearances provided higher magnitudes of mean velocity, turbulence kinetic energy as well as its dissipation rate near the top surface of the tank. This phenomenon is extremely suitable for surface aeration process in wastewater treatment plants which leads to superior mixing and transfer of oxygen from atmosphere to the water. The lower clearances developed strong axial pumping action and maintain sufficient values of radial velocity and turbulence quantities till the tank wall which helps in solid-liquid suspension process in the agitated vessels at low power consumption.

The effect of impeller diameter ranging from $D/T = 0.2$ to 0.46 (fully turbulence regime) on flow hydrodynamics in RT stirred tank was investigated through CFD simulations. The magnitudes of power number as well as radial pumping number increase slightly with impeller diameter. The power number calculated using energy dissipation rate was found to be lower than that calculated by torque and the overall percentage deviation was found to be 15%. The distribution velocity field and turbulence kinetic energy increased with increase in impeller diameter. The peak value of mean velocities and turbulence parameters were observed at angle of 50° behind the impeller blades.

Chapter 1

Introduction

Mixing and agitation in stirred vessels are widely used unit operations in the various process industries such as chemical, pharmaceutical, food, oil, and bio-chemical as well as municipal and industrial wastewater treatment plants to enhance the mass and heat transfer rate. Superior mixing of contents is the prime importance for producing high yields of product. In comparison to worlds' chemical production, more than 50% processes involve stirred tanks for production of high value added products (Hemrajani and Tatterson, 2004). The main objectives of mixing process in stirred tanks are to achieve the uniform concentration of contents, physical properties and temperature. Mixing in stirred vessels is carried out by the physical movement of contents by rotating impellers which generates complex and three dimensional flow structure. Stirred tanks have been used for various industrial applications and these are classified based on the number of phases involved in the tanks (Table 1.1).

Table 1.1 Some industrial applications of stirred tanks (Ranade, 2002; Debangshu, 2007)

Phases handled	Applications
Liquid	Alkylations, sulfonations, esterifications, bulk and solution polymerizations (styrene, acrylonitrile, ethylene, propylene)
Gas-Liquid	Oxidations (ethylene, paraffins), chlorinations (acetic acid, dodecane), carbonylations (methanol, propanol), manufacture of sulfuric acid, adipic acid, oxamide, esterifications
Gas-Liquid-Solid	Hydrogenations (olefins, edible oils, several chloro and nitro aromatics), oxidations (p-xylene), fermentations (alcohol, single cell proteins, antibiotics), wastewater treatment
Liquid-Liquid	Suspension and emulsion polymerizations (styrene, vinyl chloride), extractions
Liquid-Solid	Calcium hydroxide (from calcium oxide), regeneration of ion exchange resins, anaerobic fermentations
Gas-Liquid-Liquid	Bi-phase hydroformylations, carbonylations

In stirred tanks, scaling of tank affects flow hydrodynamics and finally its performance. It is reported that the small scale stirred tanks have higher shear rate and high circulation rate compared to large scale tanks. Hence, the analysis of scale-up/scale-down of stirred reactors is crucial for the pilot plant tests (Ranade, 2002). A different types of impellers with different shapes have been used in practice. Impellers located at different clearances are used for different applications. A stirred reactor has to perform several functions simultaneously for many industrial situations. For example, blending and heat transfer processes require more bulk flow and less shear, while gas-liquid dispersion and mass transfer processes requires high shear rate (Tatterson, 1991). Hence, it is difficult to get the desired flow hydrodynamics for such a conflict requirement. The cost of production in US chemical industry through stirred tank was half of the \$750 billion per year and \$20 billion per year was the major loss to the industry due to inefficient design of stirred tanks (Roy et al., 2010). A compromise between conflicting process requirement needs to be achieved in order to get the desired output. Hence, in the optimal design and process economic point of view, it is the job of reactor engineer to have a prior knowledge of complex flow hydrodynamics and its relation with design parameters and with process of interest.

1.1 Stirred Tank Technology

A conventional stirred tank comprises of vertical cylinder, a rotating impeller mounted on a vertical shaft (Figure 1.1). Sometimes, horizontally placed, or square or rectangular shape of stirred tanks are also used and these are called as nonstandard geometries. The stirred vessel consists of several components such as rotating impeller, shaft, wall baffles, motor drive and gear box. Sometimes impellers with bottom entrance can be used in tall tanks to reduce shaft length and maintain mechanical stability. For the large product storage and blending tanks impellers with side entrance or entering from top at an angle for unbaffled tanks can be used. Mixing in stirred tank takes places under laminar regime or turbulence regime. It is decided

based on the impeller Reynolds number and it is defined as $N_{Re} = \frac{ND^2\rho}{\mu}$. N represents the

rotational speed of impeller, D is the impeller diameter, ρ and μ are density and dynamic viscosity of fluid respectively. When the Reynolds number is below 10, the flow condition becomes laminar and when its value is more than 10^4 , the flow is fully turbulence. The flow is considered to be transitional when Reynolds number finds in between above mentioned two regimes (Bates et al., 1963). The various components of stirred tanks are explained briefly in the following section.

Figure 1.1 A conventional stirred tank

1.1.1 Rotating Impellers

Rotating impellers are broadly classified based on the flow patterns generated and specific application for which these are employed. The commonly used impellers are given as:

Radial flow impellers – Disk turbine (Rushton), flat blade impeller, hollow blade turbine

Axial flow impellers – Propeller, pitched blade turbine, hydrofoils

Maximum input energy provided for radial flow impellers is used for generating turbulence while axial flow impellers consume it for convection. Radial flow impellers are extremely suitable for the process involving gas-liquid, liquid-liquid and multiphase dispersions. While, axial flow impellers are employed for the process involving suspension of solids, enhancing the heat transfer rate and blending.

The commonly used different types of impellers in mixing processes are shown in Figure 1.2 (a-d). Marine propeller is the axial type of impeller which is often used for large tanks with side entrance and small tanks with top entrance. These are generally operated at high speed and used for low viscosity liquids. Flat blade impeller and disk turbine are the radial type of impellers and these are used for low to medium viscous fluids. These impellers produce high

levels of turbulence and shear in comparison with axial flow impellers. The difference between flat blade impeller and disk turbine is that, without disk, impeller discharge stream does not move completely in the radial direction because of pressure difference created between each side of impeller. Disk turbine is more power intensive and produces uniform radial discharge than the flat blade impeller. Even though pitched blade turbine comes under the category of axial flow impeller, it is mixed flow impeller as it generates the flow pattern in both radial as well as axial direction. If the ratio of impeller diameter to tank diameter ratio goes above 0.55, pitched blade turbine behaves like radial flow impeller (Joshi et al., 2011).

Figure 1.2 Different types of impellers, marine propeller (a), flat blade impeller (b), disk turbine (c), and pitched blade turbine (d) (Walas, 1990; McCabe et al., 1993)

1.1.2 Wall Baffles

Baffles are commonly employed for turbulence and transitional mixing processes. Generally, baffles are not used in case of laminar mixing. Wall baffles consists of flat plates attached to wall of mixing tank to alter the tangential flows produced by rotating impellers and enhance the mixing quality. Baffles disturb the solid body rotation and transform the tangential flows into axial flows. Baffles increase the drag in the flow while it consumes more power for the rotation of impellers. Stirred tanks are commonly employed with three or four baffles (Torre et al., 2007).

1.1.3 Bottom of Tank

Cylindrical stirred tanks comprise of flat or dished bottom. The tanks with different bottoms generate the different flow patterns below the impeller and result in different mixing efficiencies. The dished bottoms are preferred for solid suspension process, because solids accumulate at the corner of flat bottom tanks.

1.1.4 Motor and Gear Box

The motor and gear box comprises the drive system of stirred tank. A gearbox is used to obtain the required impeller rotational speed from the motor speed.

1.2 Impeller Characteristics

The flow characteristics of different impellers are represented in terms of power number, pumping number and flow patterns.

The power applied to stirring process produces volumetric circulating capacity (Q)

$$Q \propto ND^3 \quad (1.1)$$

Where Q (m³/s) represents fluid circulation rate, N (rev/s) is impeller rotational speed and D (m) is the impeller diameter.

1.2.1 Impeller Pumping Capacity and Pumping Number

Pumping capacity of the impeller represents the amount of fluid discharged by the rotating impeller. After solving Equation 1.1, it can be written as

$$Q = N_Q N D^3 \quad (1.2)$$

Where, proportionality constant N_Q represents the impeller pumping number which depends upon the impeller diameter (D) to tank diameter (T) ratio and impeller Reynolds number.

The values of N_Q for commonly used impellers under turbulence flow conditions are given in Table 1.2.

Table 1.2 Type of impellers with their pumping number (N_Q) under turbulence flow conditions (Walas, 1990)

Type of impeller	N_Q
Marine Propeller	0.4-0.6
Disk flat blade turbine (Rushton turbine)	0.72
Pithed blade turbine	0.79
Hollow blade turbine (Smith)	0.76
Flat blade turbine	0.7
Hydrofoil impellers	0.55-0.73

1.2.2 Power Consumption and Power Number

The power required for mixing process is defined as

$$P = N_p \rho N^3 D^5 \quad (1.3)$$

where N_p represents the power number. N_p depends on the impeller type and impeller Reynolds number (N_{Re}). Relationship between N_p and N_{Re} for various impeller designs is shown in Figure 1.3. It is observed that impeller blade width, number of blades, blade angle, the impeller to tank diameter ratio, baffle configuration affects the power number. N_p sharply decreases with $N_{Re} < 10$ (laminar regime), it changes slightly for $10 < N_{Re} < 10^4$ (transitional regime) and becomes constant for $N_{Re} > 10^4$ (turbulence regime).

Figure 1.3 Relationship between power number and impeller Reynolds number for various impeller designs (Bates et al., 1963)

1.3 Flow Patterns in Stirred Tanks

Each impeller with its characteristic flow pattern results in different levels of shear rate and pumping capacity. Mostly, axial flow impellers provide high pumping and low-shear while radial flow impellers provide high-shear but low pumping.

The flow patterns produced by impellers result in different mixing efficiencies. The typical flow patterns produced by axial as well as radial type of impellers are shown in Figure 1.4(a-

b). The single loop flow pattern throughout the entire vessel volume is provided by axial flow impellers (Figure 1.4a) such as pitched blade turbines and hydrofoils. The pitched blade turbine (PBT) is a mixed flow impeller which provides high pumping capacity and shear rate as well. PBT has a high shear and turbulence level in comparison with hydrofoils, however both have the same pumping capacity.

The classical flow pattern of two circulating loops one below and one above the impellers is generated by radial flow impellers as shown Figure 1.4(b). In stirred vessels, distribution of shear rate and energy dissipation rate varies with the flow pattern. The impeller which is suitable for a particular operation can be employed based on the flow patterns and shear rates. The double circulation loops associated with disk impellers are efficient for gas-dispersion operation while single circulation loop associated with axial flow impeller is well suited for liquid blending operation. The classical flow patterns generated by impellers can be transformed with the proper adjustment of geometrical parameters such as location of impeller, diameter of impeller, use of impellers and by baffling etc. (Montante et al., 1999; Ranade, 2002; Joshi et al., 2011).

Figure 1.4 Flow patterns for different impellers (Walas, 1990)

The mixing process in a stirred tank is strongly affected by the complex and the turbulence flow hydrodynamics. Hence, for optimal design of stirred tanks, it is of prime importance to have a knowledge of flow hydrodynamics, mixing level and overall performance of stirred reactor (Yapici et al., 2008). To have more insights in these aspects, efforts have been done over last three decades through the experimental fluid dynamics and Computational Fluid Dynamics (CFD). In the following sections, both experimental and CFD approaches are explained for the estimation of flow fields.

1.4 Experimental Techniques for Velocity Measurement

Various experimental techniques have been used for the measurement of flow fields in processes involving single phase and multiphase as well. However, each of the techniques have their merits and demerits (Chaouki et al., 1997). Generally, these measurement techniques can be classified into invasive and non-invasive. The details of these measurement techniques have been presented in the following section.

1.4.1 Invasive Velocity Measurement Techniques

The invasive techniques disturb the flow during the velocity measurement, wherein the probe needs to be inserted into the phase flow under consideration. Some of the widely adopted invasive techniques for the velocity measurement are briefly described as below.

(i) Pitot Tube

The Pitot tube works on the principle of measuring the pressure difference at a given location in the flow field. In this, the direct pressure of flow is measured at the point of contact pitot tube and another measurement is the static pressure. The difference between direct pressure and static pressure gives the dynamic pressure. Then the flow rate is determined by taking square root of dynamic pressure and subsequently flow velocity can be obtained. This technique has advantages of low cost, easy for installation into an existing system, however use of this technique is limited due to the difficulties in measuring two phase differential pressure and low accuracy (Ligarani et al., 1989).

(ii) Hot Wire Anemometry (HWA)

HWA technique is based on the principle of change in the electrical resistance wire due to the liberation of heat by flowing fluid and estimates the local fluid velocity with respect to change in resistance of wire. When fluid moves around the probe, it transfers a certain amount of heat by convection, which can be calibrated against fluid velocity. HWA is relatively cheaper and has a good accuracy at lesser cost. But it is not suitable for high velocity gas-solids or gas-liquid-solids systems, as the probes used in HWA are thin (Muller, 1992).

(iii) Optical Probes

The working principle of optical fibers is the difference in refractive index of different materials under consideration in flow field. In optical fiber, light emits at one end of the optical

fiber with a pulse laser and some of this light reflects back at the other end (through total internal reflection). The intensity of the reflected light can be determined by use of a photo-detector, which depends on the refractive index of the surrounding fluid optical probes are less effective for multiphase systems. (Cartellier, 1992; Xue et al., 2008).

1.4.2 Non-Invasive Velocity Measurement Techniques

The non-invasive techniques measure the velocity and velocity fluctuations without disturbing the flow in any way. These techniques are indirect measurement techniques which involve the multistep, i.e., the recorded data in form of the signals or photographs needs to be processed further to get the velocity and velocity fluctuations. Usually, these techniques involve some rigorous mathematics calculations during data processing. The non-invasive techniques are costlier than the invasive techniques due to the indirect measurement method and the associated hardware and software requirements. Some of widely used non-invasive velocity measurement techniques are briefly described below.

(i) Laser Doppler Anemometry (LDA)

In LDA, when a narrow laser beam is illuminated on fluid, the beam reflects back to the source. But there will be difference in the frequency of a laser beam received back from transmitted beam when the fluid is moving. This difference in the frequency (Doppler shift) is used to measure the velocity of moving fluid. LDA does not requires the calibration which is advantage over the use of invasive techniques. The LDA has major problem for multiphase flow monitoring, it is limited to low-volume fractions of the dispersed phase and does not provide the clear information regarding the phase holdup distributions (Rammohan et al., 2001 (a,b); Khopkar et al., 2005). LDA is restricted to transparent flows and transparent tank walls, due to the inherent use of a laser (Bashiri et al., 2016).

(ii) Particle Image Velocimetry (PIV)

In PIV, a high energy laser beam is incident through a cylindrical lens arrangement which shapes the transmitted laser beam into a thin planar sheet of high intensity laser light. Later, this sheet of laser light is aligned parallel to the fluid flow direction. The neutrally buoyant particles are seeded into the flow and these particles scatter the planar laser sheet when they pass through it. The digital camera is placed perpendicular to planar sheet which captures the photograph of scattering seed particles. After one photograph, laser sheet pulses again and again camera captures the photograph of scattering of seed particles. However, during this short

time, seed particle would have moved away to the new location in flow streamline, subsequent change is captured by the pulsing laser and associated camera. Comparing these photographs and particle position, instantaneous velocity of fluid is obtained (Li et al., 2011). With the use of laser like LDA, PIV cannot be used for multiphase systems having a high holdup of the dispersed phase (Upadhyay, 2010).

(iii) Radioactive Particle Tracking (RPT)

RPT uses γ -radiations for the measurement of flow fields. In this technique, the motion of a radioactive source emitting γ -radiations is determined by an array of scintillation detectors strategically placed around the vessel of interest. Before experiments, the radioactive particle needs to be prepared in a such way that it should mimic the flow i.e. neutrally buoyant with the phase of interest. For solid phase tracking size, shape and density of tracer particle should be similar to a solid phase and for liquid phase tracking, tracer particle should be neutrally buoyant with liquid phase (Meek, 1972; Lin et al., 1985; Moslemian et al., 1989; Devanathan et al., 1990; Degaleesan, 1997; Rammohan et al., 2001; Roy et al., 2002; Upadhyay and Roy, 2010).

During experiment, the tracer particle moves freely inside the vessel, and the position of the tracer particle is determined by an array of scintillation detectors that monitor the γ -radiations emitted by the tracer particle. The intensity of radiation recorded at each detector decreases exponentially as the distance between the particle and detector increases. In order to estimate the position of the tracer particle from the measured radiation intensities, a calibration step needs to be performed prior to the RPT experiment by placing the tracer particle at various known locations. Using the data acquired, calibration curves can be established that relate the intensity received at a detector to the distance between the tracer particle and the detector. Once the distance of the particle from the set of detectors is known, a suitable reconstruction algorithm can be used to estimate the position of the particle at a given sampling instant in time. The instantaneous velocities are calculated by time differentiation between two successive instantaneous positions. From this information, it is possible to evaluate the other flow quantities such as mean velocity, kinetic energy of turbulence, shear stresses etc. Figure 1.5 shows the steps involved in RPT for data processing. RPT has advantages over LDA and PIV, it successfully used in multiphase flows having high-volume fractions of dispersed phase such as bubble columns, liquid-solid risers, stirred tanks etc. (Rammohan et al., 2001 (a,b); Khopkar et al., 2005). RPT provides the Lagrangian information about velocity fields and turbulence parameters, however LDA gives Eulerian data (Bashiri et al., 2016).

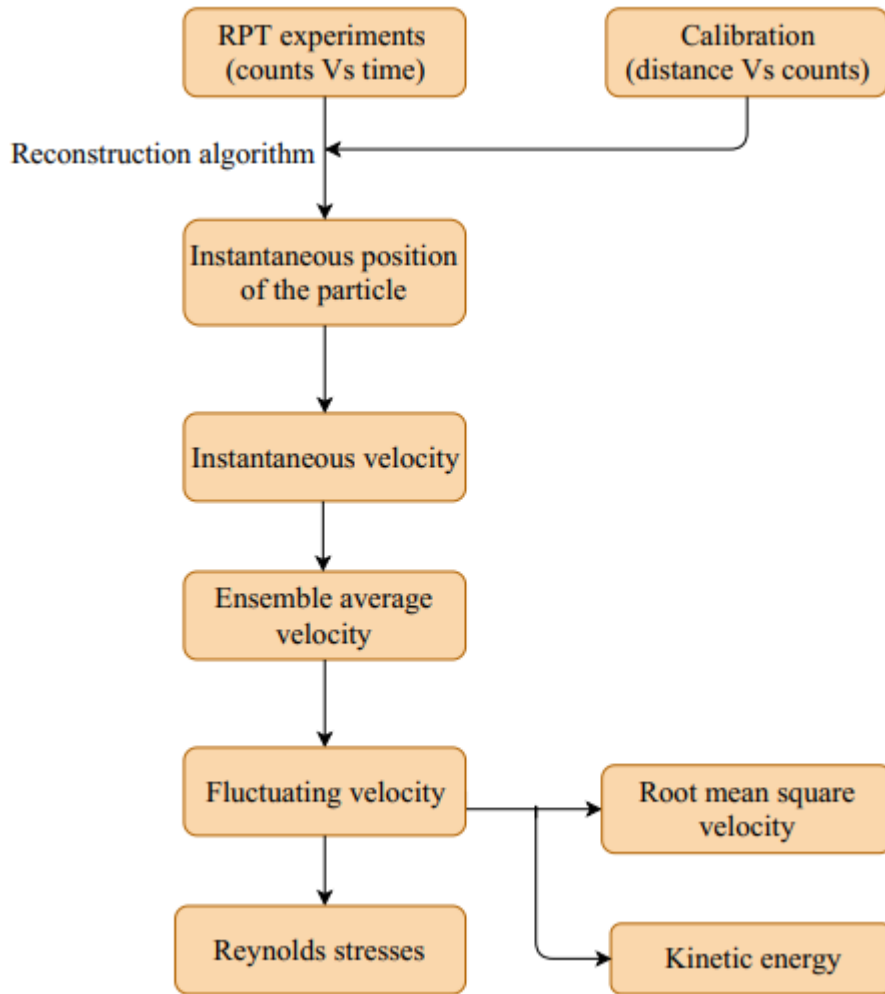

Figure 1.5 Radioactive Particle Tracking (RPT) technique data processing steps

(iv) Positron Emission Particle Tracking (PEPT)

PEPT is very similar to RPT, the motion of a γ -ray source is determined in RPT, however the motion of a single positron emitting tracer is determined in PEPT. Like RPT, the tracer particle is designed specifically to track the phase of interest. When a positron is emitted by the tracer particle, it almost immediately vanishes with the free electron present in its surrounding area, and produces a pair of 511 keV γ -ray which travel in opposite directions along straight line paths. These γ -ray photons are detected by the two large positron sensitive detectors (positron cameras) which are placed on either side of the vessel of interest. The location of the positron emitted tracer particle is then reconstructed by finding the point of interaction of the two lines that connect the location of γ -incidence. Subsequently, the velocity of positron is obtained (Wildman et al., 1999). The use of high detection system (positron camera) made limitations for widespread application of PEPT (Bashiri et al., 2016).

(v) Magnetic Resonance Imaging (MRI)

In MRI technique, high magnetic field is generated by placing magnet of power around 5 Tesla outside the reactor. A radio wave antenna is used to send the signal and then receive it back. In this technique, the phase velocity is obtained by imaging spatial variation in magnitude of magnetization. This technique has successfully measured the flow parameters such as velocity distribution, phase holdups etc. However, this technique is less attractive as it has high expenditure associated with requirement of high magnetic field (Upadhyay, 2010).

In summary, from all of these flow measurement techniques each technique has its own advantages and disadvantages. The selection of the suitable flow measurement technique can be based on the following points.

- Non-invasive nature
- Accuracy
- Suitable for single and multiphase situations
- Portable and less complex for development
- less expensive

Considering all above points, no technique satisfies all above requirement. RPT does satisfy all above requirements at acceptable level of flow measurement. Hence, RPT technique is considered in present work for flow field measurement.

1.5 Computational Fluid Dynamics (CFD)

Various sophisticated flow measurement techniques, such as LDA, PIV, PEPT and RPT have been used to study the three-dimensional, highly turbulence flow structure in stirred tanks (Wu and Patterson, 1989; Li et al., 2011; Rammohan et al., 2001; Fishwick et al., 2005; Bashiri et al., 2016). Even though these experimental studies measured flow fields accurately, these techniques are neither economical nor practical because the best choice of tank geometry and impeller type vary depending on the purpose of operation carried out in stirred tank. Different materials may require different types of impellers and tank geometries in order to get the desired product quality at reasonable operational costs. Other important parameters like impeller clearance from the tank bottom, proximity of the vessel walls, baffle length and number also affect the generated flow (Yapici et al., 2008).

With the significant improvements in computer technology and numerical techniques, CFD simulations have been widely used to solve complex fluid mechanics problems. CFD simulation provides an economical way to obtain the comprehensive information regarding flow behavior, circulation pattern and vortex structures needed for optimizing the tank design in a shorter time (Yapici et al., 2008). Therefore, rather than conducting an experimental study to understand fluid hydrodynamics inside the stirred tank, it is convenient to conduct CFD simulations. However, to test the predictive capability of CFD model, it needs to be validated with experimental data.

1.6 The Present Work

In this work, the flow hydrodynamics in a fully baffled stirred tank agitated by Rushton turbine have been investigated by using RPT technique and a steady state CFD model.

The thesis has been organized into five chapters. In Chapter 1, introduction to stirred tank technology, the flow characteristics in stirred tank and various flow field measurement techniques have been presented. Chapter 2 presents a detailed literature review with reference to RPT and its widespread application in measurement of flow hydrodynamics, various turbulence models and various impeller rotation modelling techniques used in CFD modelling of stirred tanks and experimental as well as numerical studies on investigating the effect of geometrical parameters on flow hydrodynamics in stirred tank. In Chapter 3, the details of the Materials and Methods used in the present work i.e. experimental details of RPT setup for stirred tank, CFD methodology and governing equations used in solving the flow variables have been discussed. Results obtained from the RPT and CFD studies are analyzed in Chapter 4, (Results and Discussion). In Chapter 5, conclusions drawn from the studies and scope for the future work have been presented.

Chapter 2

Literature Review

This chapter presents a detailed literature review of the previous work to identify the gaps in the literature regarding the Radioactive Particle Tracking (RPT) technique and flow hydrodynamics inside the Rushton turbine stirred tank. The chapter has been divided into the following sections.

1. Studies using RPT: This section gives an overview of literature related to implementation of RPT and its application for various single as well as multiphase systems.
2. CFD modelling of stirred tank: This section includes literature related to (i) various impeller rotation modelling approaches, (ii) various turbulence models and (iii) CFD simulations using Reynolds Averaged Navier-Stokes (RANS) equation in Rushton turbine stirred tank.
3. Effect of geometrical parameters on hydrodynamics: This section contains the literature related to the effect of geometrical parameters such as impeller clearance and impeller diameter on hydrodynamics in stirred tanks.
4. Scope and motivation for the present study: This section sets up the objectives for the present study based on the gaps found in the literature.

2.1 Studies using RPT

As part of non-invasive technique, ionizing radiation based Computer Automated Radioactive Particle Tracking (CARPT) or generally called as Radioactive Particle Tracking (RPT) technique has already been proved to be a powerful tool for modeling industrial units and process control (Degaleesan et al., 2002). RPT has been successfully implemented and used to analyze flow hydrodynamics for various kinds of single and multiphase systems such as bubble columns, gas-solid fluidized bed, circulating fluidized, stirred tank, etc. In RPT, there are several key factors such as the tracer particle selection, calibration of the detectors and signal processing which strongly affects the reliability and accuracy in measurement (Degaleesan, 2002). This section gives the details of developments in RPT and its application over the years.

Kondukov et al. (1964) introduced the concept of a single tracer particle to study phase velocities. They used six scintillation detectors to track the motion of solid phase. Due to lack of sufficient acquisition system, they could produce only qualitative information.

Meek (1972) used six scintillation detectors to identify the solid motion in a turbulent liquid. Detectors were arranged on a vertically moving carriage which was designed to move with the solid particles so that particles can be seen by detector. Meek determined the tracer locations with the help of prior calibration. Since it was very difficult for detector carriage to maintain the same speed of the tracer particle, the particle often went out of the control volume of investigation, resulting in loss of data. However, it was the first appropriate attempt for the evaluation and measurement of instantaneous velocities, ensuring RPT for measurement of flow fields.

Lin et al. (1985) developed computer automated particle tracking to investigate the solid motions in a gas fluidized bed. They prepared the tracer particle from gamma (γ) ray emitter Scandium-46 (Sc-46) source and the density of tracer particle was closely matched with solid phase under investigation. Photomultiplier tubes incorporating sodium iodide (NaI) crystals were used for continuous monitoring of γ -ray emission. Twelve detectors were used and placed in staggered configuration around the bed at three different heights with four at each level. Such arrangement has been found to be optimal as the tracer particle can be detected by all detectors. They observed the fluctuations in the signal from secondary emissions produced due to interaction of γ -rays with the bed material. Secondary emissions have low energies which was removed by employing Schmitt trigger with an adjustable threshold. Reconstruction of particle position was done with the use of weighted least square algorithm. Instantaneous solid velocities were obtained by subtracting two successive particle locations and then multiplying with known sampling frequency.

Moslemian et al. (1989) used RPT to study the solid motion in gas-solid fluidized bed. The Sc-46 was used as tracer particle in experiment. Sixteen scintillation detectors were used to track the motion of solid particle. The speed of signal acquisition was increased by using digital pulse counting system which resulted in increase of accuracy of position reconstruction. The instantaneous velocity was obtained by time differencing the instantaneous position. The percentage error in the mean velocity measurement was found to be 2-5 %.

Devanathan et al. (1990) used first time CARPT for tracking the liquid flow in gas-liquid bubble column. Experiments were conducted in 12-inch column for the air water system. The

radioactive particle was made by embedding Scandium cylinder (1mm diameter and 0.7 mm long) into 2.4 mm diameter polypropylene sphere such that the composite particle density was 1.01 g/cc and made it neutrally buoyant with water. The particle was activated to Sc-46 with source strength of 200 μ Ci. Sixteen NaI scintillation detectors were used to monitor the particle position in the column. The data was acquired at sampling rate of 33 Hz for 5 hours. Weighted linear regression scheme as described by Lin et al. (1985) was used for particle position reconstruction.

γ -radiations sensed by detectors were converted into current signal and then amplified by fast filter amplifier. A signal discriminator was used to remove the secondary γ -emissions produced due to interaction of primary γ -radiations with column and its contents. With the use of CAPRT, they investigated mean liquid circulation profiles and liquid phase turbulence (mean velocity, Reynolds shear stress and eddy viscosity). Later, experiments and CFD simulations were conducted by researchers to investigate the particle paths through bubble column (Devanathan et al., 1995).

Yang et al. (1992) used RPT in gas-liquid bubble columns with different diameters (0.114, 0.192, 0.292 m) and height (height to diameter ratio varied from 2.5 to 8) at varying gas superficial velocities from 0.02 m/s to 0.184 m/s. They used sixteen scintillation detector system. They adopted the similar hardware for signal processing and data acquisition system which was used by Devanathan et al. (1990). In their setup, the interaction of γ - rays with the detector crystal generated the photoelectric pulse from photo-multiplier tube (PMT) of the detector. This signal was made to pass through a separate timing amplifier which amplified the weak signal. The main development brought in this setup was the manner by which the acquired information (photon counts) were stored, through which long acquisition times for the RPT experiment became possible. The tracer particle (density 1.01 g/cc) was prepared from Sc-46 and made neutrally buoyant with water. This tracer particle preparation method was also an important development in RPT.

Yang et al. (1993) found that the liquid flow pattern in bubble column is a single re-circulation cell where the gas drives the liquid to ascend at the centre of the column and descend near the wall. They evaluated both axial and radial normal stresses, shear stresses and found that both the types of stress increases with increase in gas superficial velocity. Axial normal stresses were found to be significantly higher than radial normal stresses.

After Devanathan et al. (1990) and Yang et al. (1993), the major developments in RPT were brought by Larachi et al. (1994, 1995, 1997). Larachi et al. (1994) used RPT to track the solids motion in three phase fluidized bed reactor. They used eight NaI scintillation detectors to monitor γ -ray. The tracer particle was prepared from a mixture of soda ash lime powder and scandium oxide melted at high temperature. The particle was coated with a diamond-like carbon layer in order to prevent its rupture due to erosion in flow. The density of prepared tracer particle was matched with solid phase of interest. Larachi et al. (1994) introduced Monte-Carlo model for the first time in RPT. They used Monte-Carlo model to generate distance-count map (i.e., functional relationship between the distance between radioactive source and detector, and the radiation photon counts recorded at detector) for various known locations. During calibration, they verified the count rate calculated by Monte-Carlo model with the count rate measured in actual experiments for 19200 known locations. Once the distance count map was obtained, least square approach was used for reconstruction of particle position. They were able to obtain the solid phase velocities with adequate precision.

The capability of developed Monte-Carlo model was tested by Larachi et al. (1995, 1997) by performing experiments in both the spouted bed and the fluidized bed under the actual flow conditions. Later, test of Monte-Carlo model was performed on circulating and turbulence gas-solid fluidized bed. They found that the spatial resolution was improved by increasing the number of detectors, reducing the distance between column walls and the detectors and increasing sampling time (Larachi et al., 1995).

Degaleesan (1997) and Degaleesan et al. (1998, 2001) used RPT for investigation of flow hydrodynamics in bubble columns. Degaleesan et al. (1998) studied the liquid back mixing and axial dispersion coefficient in bubble column. The fluid dynamic parameters such as time averaged velocities and eddy diffusivities needed for the evaluation of axial dispersion coefficient were obtained through RPT experiments. Further, they studied the effect of operating conditions i.e. column diameter and gas superficial velocity on axial dispersion coefficient.

Godfroy et al. (1997) used artificial neural network (ANN) algorithm for real time flow visualization. It is less time consuming than the least-square (Devanathan, 1991). It directly calculates the tracer position from the detector signals. In this algorithm, some part of the calibration data was used to design the ANN model and to obtain the model constants

(weighting functions) and the remaining data was used to check the accuracy of the model. This model used a large number of fitting parameters (159) and that need to be tuned as per required accuracy, which is the major drawback associated with the ANN model. They reported that the accuracy of ANN was less compared to that of Devanathan et al. (1990). However, the major advantage was the ability of real-time reconstruction and quick convergence.

Degaleesan et al. (2001) performed RPT experiments in bubble columns for air-water system. The experiments were conducted in different flow regimes, different sizes of bubble columns, different distributor configuration. Velocity vector plot, Reynolds stresses, turbulence kinetic energy and eddy diffusivity were obtained for all the conditions.

Rammohan et al. (2001a) implemented RPT for the first time in the investigation of flow hydrodynamics in a single phase Rushton turbine stirred tank. Researchers used sixteen scintillation detectors to track the motion of tracer particle. They found that conventional laser based techniques take more time than RPT for data collection. RPT was able to capture key phenomena of stirred tank i.e. eye of re-circulating loops above and below the impeller and shapes of the dead zones at the tank bottom. In extension of this work, Rammohan et al. (2001b) investigated the various flow parameters such as radial pumping number, mean radial velocity, mean tangential velocity and turbulence kinetic energy and these parameters were found to be in a reasonable agreement with experimental techniques like LDA and Hot Wire Anemometry (HWA). They found that RPT experiments have limitations over the large tracer particle size which was found during the comparison of fluctuating components like root mean squared error and turbulence kinetic energy.

Rammohan (2002) found an error during measurement called as ‘dynamic bias’. The tracer particle is stationary during calibration, while during the experiments tracer particle is in motion. In experiments, even in a short time period of acquisition, the tracer particle may be forced to move in the domain when the fluid is moving at high speed. Reconstruction algorithm would take a single position of tracer particle while it may be moved to another position, resulting to dynamic bias in the reconstructed positions. Such bias depends on the past particle trajectory, fluid velocity and the sampling rate. He suggested that if fluid velocity increases, the rate of data sampling needs to be increased, so that effect of dynamic bias can be minimized.

In order to implement RPT for large scale plants, careful and systematic planning is required. Roy et al. (2002) developed Monte-Carlo nuclear radiation based model for an optimal design of RPT experiments. They defined the two terms as resolution and sensitivity to predict the

optimal configuration of RPT setup in terms of source strength, detector size, shape and number of detectors and their configuration.

Degaleesan et al. (2002) proposed filtering algorithm based on wavelet analysis for the removal of intrinsic noise in the instantaneous position data generated in CARPT experiments for bubble column. They got some important findings with the use of wavelet based filtering algorithm as it removed 80-90% noise in the data and it is more suitable than the Fourier transform based algorithm for removal of such type of noise.

Bhusarapu (2005) used RPT experiment to study the hydrodynamics in gas–solid circulating fluidized bed. Sc-46 radioactive source was used for tracer particle. He made the tracer particle similar to solid particles in shape size and density, having a very small diameter 0.15 mm. He used twenty scintillation detectors to monitor motion of solid phase. The use of cross-correlation model for reconstruction of tracer particle position was the novelty in the work. With the help instantaneous position data, instantaneous and mean velocities, Reynolds stresses, turbulence kinetic energy, dispersion coefficient and time of flight for gas-solid fluidized bed were evaluated.

Khopkar et al. (2005) used CAPRT to characterize the flow generated in a gas-liquid Rushton turbine stirred tank. CARPT was able to capture the Eulerian liquid flow characteristics. Guha et al. (2007) studied the solids flow field in solid–liquid suspensions in a Rushton turbine stirred tank. They used sixteen scintillation detectors to monitor the motion of solid phase. CARPT provided Lagrangian solid flow field which was used to obtain the time-averaged velocity fields and the turbulence quantities. CARPT provided the solids sojourn time distributions at various axial location in the tank.

Upadhyay et al. (2010) used RPT to study hydrodynamics of binary mixture fluidized bed for particles having same size but different densities. They investigated the effect of air inlet velocity and bed composition on hydrodynamics and mixing behavior. Upadhyay et al. (2013) investigated the liquid flow patterns in rectangular air-water bubble column. Through RPT, the effect of different operating conditions and different aspect ratio of column on flow fields were investigated.

Dube et al. (2014) introduced an optimization strategy to find optimal positions of scintillation detectors and orientations used in the RPT setup. In this strategy, the objective function was to maximize the resolution of detectors and a mesh adaptive direct search algorithm was used to solve the optimization problem. The detector configuration suggested by this strategy was

found to be similar with Roy et al. (2002). They observed that optimization technique leads to a considerable reduction in the error during tracer particle reconstruction. They recommend that depending on the experimental conditions, the objective function may be sensitive to both resolution as well as sensitivity, while this strategy was based on resolution only.

Bashiri et al. (2016) used RPT to analyze the fully turbulence fluid flows in stirred tank equipped with Rushton turbine and pitched blade turbine. They benchmarked the RPT measurements with their CFD simulations and LDA measured literature data for Rushton turbine. RPT measured mean velocities at various axial locations were found to be in good agreement with other methods. Poincare maps for visualization of flow structures in stirred tanks and mixing time were well predicted by RPT.

Sharma et al. (2017) used RPT-Time of Flight and RPT-Volume of Fraction for oil-water two phase flow measurement in coiled geometries. RPT-Time of Flight was able to measure the exit age distribution which provided an accurate extent of radial mixing. RPT-Volume of Fraction measured occurrence density distribution. Through both methods, they collected the phase holdup and mixing behavior information by which different flow regimes in two-phase coiled flow were identified. Azizi et al. (2017) and Kalaga et al. (2017) investigated the flow hydrodynamics in bubble column using RPT. RPT efficiently provided the information about fractional gas distribution, axial mean liquid velocities and liquid phase mixing characteristics.

Kalo et al. (2019) investigated the hydrodynamics of binary gas-solid fluidized bed using RPT. They used twelve scintillation detectors to track the solid motion. Sc-46 was used as radioactive source and the tracer particle was made with the same shape, size and density of solid under consideration. They performed time series analysis to study the bed dynamics at different gas inlet velocities and bed compositions. They evaluated the Hurst exponent, autocorrelation coefficient and mixing index by using time series data.

Al-Juwaya et al. (2019) used RPT for first time to study the hydrodynamics and mixing behavior of binary solids mixture in gas-solid spouted bed. The binary mixture was prepared from glass beads and steel particles. Two separate tracer particles were prepared for glass and steel. For glass, a radioactive source Cobalt-60 (Co-60) having diameter of 0.6mm was encapsulated in an Aluminium particle to get the same density of the glass beads. For steel, a radioactive source Cobalt-60 (Co-60) was encapsulated in a steel particle to get same density like steel particles. They found that segregation always takes place in binary spout bed due to the dissimilar behavior of different solids phases in terms of the solids velocity field and

turbulence parameters. They demonstrated that, the particle-particle interaction between solids having same size but different densities play an important role for hydrodynamics in binary spout bed.

2.2 CFD Modelling of Stirred Tank

In baffled stirred tanks, rotating impellers generate highly turbulent and complex three-dimensional flow structure, as the flow induced by them interacts with the stationary baffles mounted on the tank wall. The flows in stirred tank can be modelled by two approaches, the phenomenological models and the numerical solution of the complete Navier-Stokes equations. The phenomenological models oversimplify the complexity of flow and hence these models can represent only mean velocity fields (Rammohan, 2002).

In order to capture the three-dimensional flow structure in stirred tank, rigorous numerical models are needed. With the advancement in computer technology, CFD techniques based on the Navier-Stokes are being used to solve such a complex flow structure in stirred tanks. The flow field prediction in stirred tanks through CFD is achieved by the turbulence models and impeller rotation model. The details of these aspects are given the following sub-sections.

2.2.1 Modelling of Turbulence

For optimal design of stirred tanks, engineer should have knowledge of velocity and turbulence parameters distributed in space and time domain. The transport equations for incompressible **Newtonian fluids** are given as follows. These are the continuity and momentum equations and referred as Navier-Stokes equations.

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (2.1)$$

$$\frac{\partial(\rho u_i)}{\partial t} + \frac{\partial(\rho u_i u_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left[\mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \frac{\partial u_k}{\partial x_k} \delta_{ij} \right) \right] + \rho \vec{g} + \vec{F} \quad (2.2)$$

These transport equations are solved in three ways in CFD, i) direct numerical simulations (DNS), (ii) large eddy simulations (LES), and (iii) Reynolds-averaged Navier-Stokes (RANS) equations. These approaches are represented on an energy spectrum which is shown in Figure 2.1 (Joshi et al., 2011). Energy spectrum tells the transfer of energy from large scales of motion to the small scales. Energy containing eddies contain most of the kinetic energy whereas the smallest eddies are responsible for the viscous dissipation of turbulence kinetic energy. At intermediate scales, there is neither a direct forcing of the flow nor a significant amount of viscous dissipation, but there is a net nonlinear transfer of energy from the large scales to the small scales. This is called as inertial subrange. In the inertial subrange, negligible dissipation occurs and the dominant energy process is the transfer of kinetic energy from large eddies to smaller eddies by inertial forces (Hemrajani and Tatterson, 2004).

DNS solves the transport equations directly, but it requires huge computational cost. Due to the high computational cost, the transport equations can also be solved using LES and RANS approaches. LES and RANS use the turbulence models and solves the additional equations which arises from space filtering (LES) or ensemble averaging (standard $k-\varepsilon$ model) in Navier-Stokes equations. The overall classification of strategy to solve the Navier Stokes equation is shown in Figure 2.2.

Figure 2.1 CFD model equations based on energy spectrum (Joshi et al., 2011)

Figure 2.2 Overall classification of CFD models for stirred tanks

(i) Direct Numerical Simulation (DNS)

DNS does not require any turbulence modelling, as all the transport equations are solved exactly. All the scales ranging from small scales (Kolmogorov length scale) to the largest scales are resolved in DNS. For that, accurate estimation of derivatives in RANS equations are required. Earlier, spectral methods are used in DNS method for simple geometries to estimate the derivatives and these methods are extremely accurate. With the advancement in computational technology, numerical techniques such as finite difference and finite element methods are used for DNS computations in the complex geometries like stirred vessels. However, computations using DNS are highly time consuming and requires the large storage space and hence DNS computation are limited to simple geometries and at low Reynolds number (Dewan et al., 2006; Buwa et al., 2006).

Bartels et al. (2000) used RANS based standard $k-\epsilon$ model and DNS approaches for modelling stirred tank agitated by flat blade disk turbine at low Reynolds number of 7275 and compared their results with Schafer et al. (1998). DNS as well as $k-\epsilon$ model qualitatively predicted the flow fields. In comparison, DNS accurately predicted the secondary vortical structure behind the blades, however, $k-\epsilon$ model was unable to capture it. The turbulence kinetic energy and its peak close to the impeller was well predicted by DNS, while, $k-\epsilon$ was able to do the same in the region away from the impeller.

(ii) Large Eddy Simulation (LES)

In this approach, the small scale eddies are modelled with the help of subgrid scale (SGS) models, while, large scale eddies are resolved. The SGS models properly incorporates distribution of energy transfer from the large scales to small scales.

The flow fields in the Navier-Stokes equations are decomposed into a large-scale and a small-scale component.

$$u = \bar{u} + u' \quad (2.3)$$

By putting the above decomposition in the Equations 2.1 and 2.2, taking constant density (incompressible flow), the modified equations are written as.

$$\frac{\partial \bar{u}}{\partial x_i} = 0 \quad (2.4)$$

$$\frac{\partial \bar{u}}{\partial t} + \frac{\partial (\bar{u}\bar{u})}{\partial x_i} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \nu \frac{\partial^2 \bar{u}}{\partial x_i^2} - \frac{\partial \tau}{\partial x_i} \quad (2.5)$$

Subgrid scale models such as Smagorinsky model, scale similarity model, etc are required to estimate the effect of subgrid scale stresses (τ).

LES investigations have important advantages - these are cheaper than the experimental measurements and provide the detailed three dimensional flow structure. Even though LES requires less computational cost compared to DNS, LES still needs high computational power for the optimization of complicated process equipment (Buwa et al., 2006).

(iii) Reynolds Averaged Navier-Stokes (RANS) Approach

RANS is another approach which has been used to solve flow problems in stirred tanks. It is computationally less expensive compared to LES as well as DNS and hence it is extensively used for practical engineering applications (Khopkar et al., 2004; Li et al., 2004). In this approach, basic Navier-Stokes equations are ensemble averaged, then the modified equations can be written in following form.

$$\frac{\partial \langle u_i \rangle}{\partial x_i} = 0 \quad (2.6)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_i u_j) = & -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left[\mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \delta_{ij} \frac{\partial u_k}{\partial x_k} \right) \right] \\ & + \frac{\partial}{\partial x_i}(-\rho \overline{u'_i u'_j}) + \rho \vec{g} + \vec{F} \end{aligned} \quad (2.7)$$

The Reynolds stresses term $(-\overline{\rho u'_i u'_j})$ in Equation (2.7) coming out due to the ensemble averaging, it can be modelled using Boussinesq hypothesis :

$$-\rho \overline{u'_i u'_j} = \frac{2}{3} k \rho \delta_{ij} - \mu_t \left(\frac{\partial \langle u_i \rangle}{\partial x_j} + \frac{\partial \langle u_j \rangle}{\partial x_i} \right) \quad (2.8)$$

The effective viscosity (μ_t) in Equation 2.8 can be defined by various turbulence models reported in literature from simplest zero-equation model to most complex Reynolds stress model (RSM). The commonly used RANS based turbulence models are discussed in the following section.

Standard k - ε Model

The basic assumptions associated with the Standard k - ε model are isotropic turbulence condition and high Reynolds number. In this model, μ_t is determined using kinetic energy of turbulence (k) and its dissipation rate (ε) and the modified equation is given by:

$$\mu_t = C_\mu \rho \frac{k^2}{\varepsilon} \quad (2.9)$$

k - ε model results in additional five different turbulence parameters C_μ , $C_{\varepsilon 1}$, $C_{\varepsilon 2}$, σ_k and σ_ε . These turbulence parameters have been obtained from experimental studies. The standard k - ε model predicts the flow fields satisfactorily in many studies but inaccurate prediction of turbulence kinetic energy distribution due to isotropic nature of model.

Zonal Model

In this model, whole fluid domain is divided into various small zones. Sahu et al. (1998) employed the zonal model for investigation of hydrodynamics in stirred tanks. It has significant advantages, as it identifies the different zones having a specific flow structure and determines the value of turbulence parameters accordingly for further modifications.

Renormalized Group (RNG) k - ε Model

This is two equations based model which are obtained from renormalized group methods. In RNG k - ε model, the inertial sub-range eddies are removed from eddy viscosity equation. This model efficiently predicts the turbulence quantities. It is more fundamental compared to semi-empirical models and appropriately predicts flows near the wall (Joshi et al., 2011; Ansys theory guide, 2013).

Multiscale Models

The non-spectral energy equilibrium and two time scales assumptions based multiscale model was developed by Placek et al. (1986). The standard $k-\varepsilon$ model assumes equilibrium spectrum and hence a single time scale. As mentioned earlier (Figure 2.1), the CFD simulation models are divided into three energy spectrum regions viz., production region, a transfer region and turbulence dissipation region. The multiscale model has two time scales for the production region and turbulence dissipation rate region. This model consists of two equations, one for the transport of kinetic energy of turbulence of the large-scale vortices and second one for transport of kinetic energy of turbulence of inertial sub-range eddies. It is well suited for the prediction of flow patterns in stirred tanks.

Reynolds Stress Model (RSM)

RSM assumes the isotropic flow condition, also, it properly incorporates streamline curvature, rotational strains and body force effects (Murthy et al., 2008). It is seven equations based model which solves six equations for the Reynolds stresses and one equation for turbulence energy dissipation rate. In RSM, the model parameters for Reynolds stresses are not constant and it varies with the type of flow and hence model needs to be calibrated. It takes the large computational power to get the converged solutions for the system with complex flow. These are the major disadvantages associated with the use of RSM which make its less attractive.

2.2.2 Modelling of the Impeller Rotation

In the CFD modelling of stirred tanks, the impeller rotation can be modelled by the various techniques and these are broadly classified into steady state and unsteady state.

Steady state techniques

The model equations associated with these techniques are solved under steady state condition. Some of the steady state techniques are briefly described in this section. Figure 2.3(a-d) shows the schematic representation of various impeller rotation modelling techniques.

(i) Impeller boundary condition technique (IBC)

In this technique, impeller is considered as a black box (Figure 2.3-a). The impeller is encapsulated with the surface area around it and the boundary conditions are provided on it which are obtained from experimentally measured flow fields and turbulence parameters (Kresta and Wood, 1991). The boundary needs to be changed, if the tank or impeller

configuration changes. After providing boundary conditions, the solution for flow variables for entire flow domain is obtained. The dependency on experimental boundary conditions is the major drawback associated with the use of this technique. It is difficult to predict the fluid dynamics for various tank designs and configurations; as geometrical design parameters strongly affect the flow hydrodynamics (Yapici et al., 2008). Further, it is difficult to get the exact boundary conditions from experiments for the processes involving the multiphase flows.

(ii) Source-sink technique (SS)

Source-sink technique was developed by Pericleous and Patel (1987) wherein rotating impeller is modelled as momentum source and stationary baffles are considered as momentum sinks. In this technique, the impeller blade is divided into number of vertical strips from hub to impeller tip. If the blade is placed at different angle with axis of rotation, then the strip is further divided into number of subsection so that every section (of the blade) is assumed to be practically flat. The blade section inside each strip is approximated to an airfoil and airfoil aerodynamics is applied. The tank wall, baffles and impeller blades are considered as solid surfaces for boundary conditions.

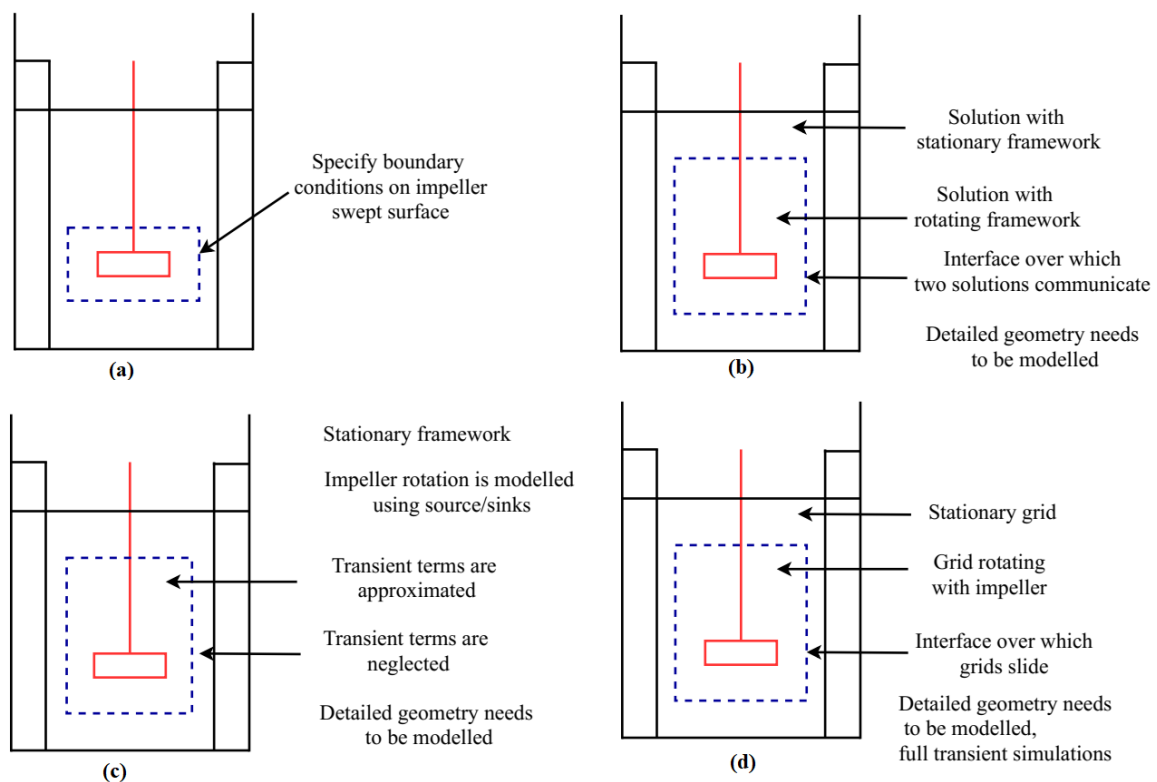

Figure 2.3 Schematic representation of various impeller rotation modelling techniques

(Joshi et al., 2011)

(iii) Inner-outer technique (IO)

IO technique has been developed by Brucato et al., (1996) and subsequently used by Daskopoulos and Harris (1996) and Brucato et al., (1998) for prediction of flow hydrodynamics in stirred vessels. In this technique, the region encapsulating the impeller is the inner region and the region of bulk flow with baffles is the outer region. The arbitrary boundary conditions are provided at surface of inner region and simulations are conducted. Thus, it has provided the flow fields and turbulence quantities inside the inner region as well as at the boundary of inner surface. This information is used as boundary conditions for the bulk flow simulations (bulk region). Now, the flow fields are known at the outer boundary surface of inner region and this information is used for second inner simulation. This iterative process continues, until system reaches to an acceptable numerical error. In this approach, a steady state assumption was used for the simulations in each of the inner as well as outer region in its own frame of reference.

(iv) Multiple reference frame technique (MRF)

MRF technique was put forward by Luo et al. (1994) for modeling of impeller rotation. In this approach, stirred vessel is partitioned into two frames, i.e. a moving frame and stationary frame. The moving reference frame encapsulates the impeller and the flow confined by it, and the stationary frame involves the vessel, the baffles and the flow outside moving frame (Figure 2.3-b). MRF approach was used by Naude et al. (1998) for modeling of baffled stirred tank with propeller rotor; the results obtained for time averaged computational mean velocities were found to be in good agreement with LDA measurements. Khopkar et al. (2004) and Dewan et al. (2006) have reported that MRF technique does not require any experimental boundary conditions and has a capability for reasonable prediction of flow fields at less computational cost.

(v) Snapshot technique

Snapshot technique was proposed by Ranade and Dommeti (1996) for modeling of impeller rotation. In this technique, the whole flow domain is divided into inner and outer regions (Figure 2.3-c). The inner region encapsulates the impeller in which time dependent terms are decomposed into spatial gradient and impeller rotation speed. However, outer region neglects the time dependent terms. The spatial derivative term is incorporated to the source term in steady state transport equation. The suction and ejection of the fluid from back and front side

of the blade have been considered by adding the mass sink and source respectively in the transport equations.

The assumptions associated with negligible time dependent terms in the outer region removes the momentum in the transport equations. This model assumes that the baffle does not affect the flow between the blades. Further, this technique is not validated for all flow variables in the entire flow domain. These are the major drawbacks of this technique.

Unsteady state techniques

Some of the time dependent impeller rotation modelling techniques are discussed in this section.

(i) Sliding mesh technique (SM)

SM is fully transient simulation technique which was developed by Luo et al. (1993). In this technique, whole fluid domain is divided into two inner and outer non-overlapping cylindrical zones (Figure 2.3-d). Both zones require separate block grid. The grid associated with the inner zone rotates with impeller, while, the grid associated with outer stationary zones remains under stationary condition. The rotating impeller blades are modelled as solid rotating walls. This technique is used for various studies, because, it does not require any kind of experimental data.

Acceleration terms needs to be added explicitly in momentum equations in order to incorporate the moving grid system. The care should be taken at the interfaces, as the inner zone grid moves with rotating impeller. The solution for this method become complex and also it requires few days to get the solution convergence. Hence, SM requires huge computational cost compared to other approaches. Due to the excessive computational cost, it restricts the use of number of cells for simulation which ultimately affects the prediction of turbulence quantities and shear rate near the blades.

(ii) Moving deforming grid technique (MDG)

Perng and Murthy (1994) proposed MDG method in which single type of time dependent grid is employed for both moving as well as stationary parts. The impeller rotation causes the movement of grid connected to it and this results the deformation of grid over the entire flow domain. The grid around the impeller rotates and after certain deformation is accomplished,

the grid is brought back to its original form and the properties are transferred to the restored grid in a conservative fashion.

In this technique, it is very difficult to maintain the grid quality which ultimately affects the numerical accuracy in the results. The computational requirement is highest for this approach compared all other impeller modelling approaches (Coroneo et al., 2011).

(iii) Impeller modelling within lattice–Boltzmann-LES framework (adaptive force field technique (AFT))

The basic assumption of this technique is that the entire flow domain constitutes of small particles. The transport equations are applied to each of these particles and form the equations like incompressible Navier–Stokes equations. This technique assumes, after each time step, each particle travels a lattice distance which was located at the corner of lattice and collide with other particle. The calculation of forces acting on flow is adjusted in such a way that the prescribed velocities at points within the domain should be maintained and this is called as AFT technique. The impeller and tank wall are considered as a set of control points on their surface. For the points on the impeller surface, the tangential velocities are provided same as that of rotational speed of impeller. The distance of surface point from axis of rotation is also provided. The tangential velocities on tank wall are set to zero. The force fields are adapted by a control algorithm at each interval in such a way that it should suppress the mismatch between actual flow velocity and prescribed values and it should provide control values at the surface points.

Even though this technique properly models the impeller rotation and provides the accurate prediction of flow hydrodynamics, still it has limitations associated with requirement of high computational power. It helps more in understanding the flows near walls and impeller swept region where measurements by experimental technique is difficult (Joshi et al., 2011).

2.2.3 CFD Simulations using Reynolds Averaged Navier-Stokes (RANS) Equation with Multiple Reference Frame (MRF) Technique in a Rushton Turbine (RT) Stirred Tanks

As explained above, the three different turbulence modelling approaches have their respective range of application, advantages and drawbacks. The model should be selected in such a way that it has to predict the results with reasonable accuracy at less computational cost. The use of LES or DNS as a research design tool makes less attractive as both approaches requires huge computational cost. In this view, RANS approach is suitable for CFD modelling of stirred tank

which gives the results with reasonable accuracy at less computational cost compared to former approaches. Similarly, MRF technique is capable of investigating the flow hydrodynamics in stirred tank with a reasonable accuracy and less computational expenses in comparison with all other impeller rotation modelling approaches.

Among the various types of impellers used in baffled stirred tanks, disk turbine (RT) is one of the most generally used and extensively studied radial type of flow impeller. In present work, CFD simulations have been conducted to investigate the flow hydrodynamics in a stirred tank agitated by Rushton turbine using RANS approach in combination with MRF technique. This section deals with literature review on various CFD studies using RANS model with MRF approach for RT stirred tank.

Luo et al. (1993) have used $k-\varepsilon$ turbulence model in combination with MRF technique for the first time. They compared only the profiles of tangential and axial velocity while no comparison of turbulence parameters was reported. Large deviations in the prediction of tangential velocity was reported, while, axial velocity was better predicted with maximum percentage deviation of 20%.

Dong et al. (1994) have employed the $k-\varepsilon$ with MRF technique to simulate the flow in stirred tank. The prediction of flow pattern was good in the bulk flow region; however radial and axial velocities magnitudes were overestimated in the impeller vicinity. Over estimation of turbulence kinetic energy was found in the impeller stream. The velocity vectors plots were accurately predicted by model.

Luo et al. (1994) used CFD model using MRF technique for impeller rotation modelling. Radial and axial velocities are qualitatively predicted by CFD model with the maximum deviation of 20% and 15% respectively. But, the tangential velocity was poorly predicted. The comparison of turbulence parameters was not provided.

Ciofalo et al. (1996) have employed MRF technique and the $k-\varepsilon$ turbulence model as well as the second-order differential stress model (DSM). The predictions of free surface shape and tangential velocity were found in good agreement with experimental results. The predicted values of power number were found considerably smaller than experimental values (15-30%).

Tabor et al. (1998) used MRF and SM techniques for modelling of impeller rotation and the standard $k-\varepsilon$ model for turbulence modelling. The flow close to the impeller was well predicted by SM, but MRF missed it. However, MRF predicted the overall vortex pattern at much lesser

computational power compared to SM. A good comparison for prediction of velocity components close to the impeller blade edges between MRF and literature was found. But, over prediction was provided by SM technique. MRF much accurately predicted the radial and tangential velocities near impeller, while considerable deviations in axial velocity were found (around 100%). Axial velocity near tank edges was well predicted with maximum deviation of less than 10% while other two components shown the maximum deviation of 30%. They found that MRF predicts the impeller stream flow behavior in much better way compared to SM.

Bartels et al. (2000) conducted the CFD simulations using standard $k-\varepsilon$ model and the DNS with MRF technique for impeller rotation modelling. They performed simulations at low Reynolds number of 7275. DNS accurately predicted the contours plots of turbulence kinetic energy compared to $k-\varepsilon$ model. DNS successfully identified the secondary vortices near the hub and disk while $k-\varepsilon$ model missed it. Simulation results by both the models qualitatively predicted the upward inclination of flow in the impeller discharge region and existence of ring vortices. Researchers concluded that the flow features predicted by both models showed good agreement while DNS shown better prediction compared to standard $k-\varepsilon$ model during close comparison.

Kukukova et al. (2005) carried out CFD simulations to investigate the flow pattern with use of one and two impellers. They used MRF along with standard $k-\varepsilon$ model. The prediction of flow fields such as radial, axial and tangential velocities were found in good agreement with those obtained from experiments. In addition, they investigated the concentration profile, mixing time, power number and impeller pumping number. The values of mixing time were under predicted compared to experiments with deviation of 20-45%.

Deglon and Meyer (2006) have conducted CFD simulations using MRF and standard $k-\varepsilon$ turbulence model. They considered four different grids and different discretization schemes such as upwind, central and Quadratic Upstream Interpolation for Convective Kinematics (QUICK) to investigate the effect on flow fields and turbulence parameters. They observed that the predictions of mean velocities were not significantly affected by either the grid resolution or discretization scheme. However, predictions of turbulence kinetic energy were strongly affected by both the grid resolution and discretization scheme. They observed that with a significant increase in grid resolution, simulation results accurately predicted the turbulence kinetic energy. Researchers concluded that poor prediction of turbulence parameters may be due to of numerical errors (grid resolution) rather than inadequacies in the turbulence model.

Guha et al. (2006) have developed CFD based compartmental model and investigated the effect of turbulence mixing on the performance of stirred tank reactors. The model was able to capture all the important features of macromixing in stirred reactor. They studied the effect of location of feed on product yield and selectivity for multiple reactions. Researchers found some important conclusions from studies such as, the consideration of dispersion term in the transport equation is important when the reactant feed point is located far from impeller. While, convection is important when reactant feed location is near to impeller.

Alopaus et al. (2009) used zonal modelling for CFD simulation. In this model, the tank volume is divided into small regions with increasing inner volume from impeller swept volume to total tank volume. They obtained the continuous small and large scale mixing curves for each volume. They investigated the two important parameters (i) pumping number and (ii) turbulence dissipation rate. They conducted various kind of simulations for varying tank size, grid size, discretization schemes, turbulence model and type of impeller.

Coroneo et al. (2011) have carried out RANS based CFD simulations and highlighted the effect numerical errors on prediction of fluid dynamics parameters. They suggested that the errors in the predictions of turbulence parameters can be considerably minimized by reducing grid size. Particularly, the deviation between the power number predicted by torque and by integration of turbulence dissipation rate decreased with decrease in grid size. They observed considerable improvement in the predictions of tracer homogenization dynamics with decrease in grid size. Finally, they concluded that the numerical errors can be reduced with the use of much finer computational grid.

2.3 Effect of Geometrical Parameters on Flow Hydrodynamics inside the Stirred Tanks

In baffled stirred tank reactors, the required mixing can be achieved with the proper adjustment of reactor hardware as well as operating conditions at less energy consumption. It is reported that the performance of stirred tank mainly depends on the geometric and dynamic parameters of the tank as well as the physico - chemical properties of the fluid. The geometric parameters include shape and aspect ratio of stirred tank, impeller clearance, impeller diameter, number and size of the impeller, width of baffles etc. (Montante et al., (1999, 2001); Karcz et al., 2005; Kumaresan and Joshi, 2006; Karcz et al., 2005; Montante et al., 2006; Ochieng et al., 2008; Rao et al., (2009, 2010); Devi et al., 2011; Joshi et al., 2011; Li et al., 2011). Among these

parameters, clearance of the impeller from the tank bottom and diameter of impeller are crucial which control the flow patterns and suitability of the stirred reactor for various processes concerned (Montante et al., 1999; Rao et al., (2009, 2010); Devi et al., 2011; Li et al., 2011; Joshi et al., 2011; Kulkarni and Patwardhan, 2014).

Generally, in a standard configured stirred tanks, the impeller is placed at the $1/3$ of tank diameter (T) from bottom of tank and the impeller diameter (D) is $1/3$ of tank diameter. However, the flow hydrodynamics in stirred tanks is considerably affected with the variation in these parameters. This section deals with review on various experimental and numerical investigations reported to analyze the effect of impeller clearance (C) and impeller diameter on flow hydrodynamics in stirred tanks.

In a standard configured stirred tank, the double loop flow pattern phenomenon i.e. one above the impeller and one below the impeller, is generally observed (Figure 2.4). However, Nienow (1968) has conducted the experiments at different impeller clearances for solid-liquid system and found that the double loop flow pattern changed into single loop flow pattern when impeller clearance is reduced to $1/6$ of tank diameter. This flow pattern resulted in different types of solid distribution throughout the tank. He concluded that suspension of solids can be achieved with lowering the impeller clearance at low impeller speed. Following this, Conti et al. (1981) have developed a correlation for estimation of impeller speed over wide range of impeller clearances. Ibrahim and Nienow (1995) observed that the radial discharge stream of RT changed to axial when the impeller clearance lowered to $T/6$, which means that double circulation loop flow patterns change to single loop flow pattern. The power consumption also dropped with lowering the clearance and the power number was reduced by 25% to that of standard clearance.

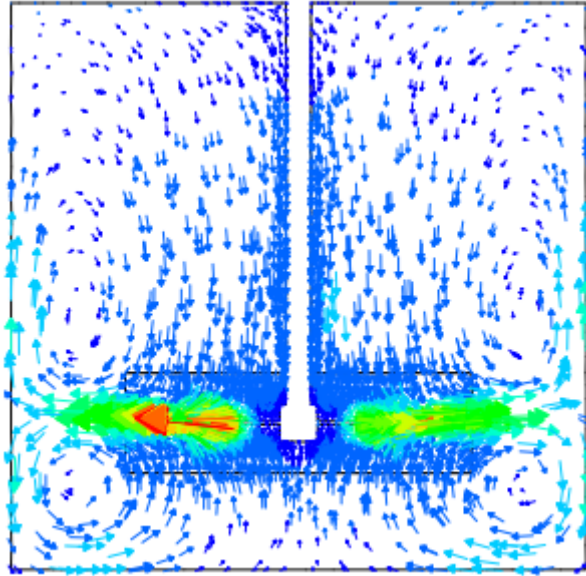

Figure 2.4 Double loop flow pattern associated with standard configured stirred tank
(Zhu et al., 2019)

Armenante and Nagamine (1998) have conducted the experiments for four different types of impeller and investigated the effect of impeller clearance on impeller speed for suspension of solids and power consumption. Further, they developed a correlation quantifying the effects of impeller clearance and other parameters on impeller speed for solid suspension when the impeller was placed near the tank bottom. They found that the mixed and axial flow impellers were more energy efficient than radial flow impellers. Researchers noticed that the minimum speed of impeller for complete suspension of solid increases with lowering C/T ratio when it approaches to zero.

Montante et al. (1999) have investigated the effects of impeller clearance and its rotational speed on flow characteristics by experimental LDA technique in Rushton turbine stirred tank. The transition of flow pattern from double loop to single loop occurred at the impeller off-bottom clearance around $T/5$ with impeller discharge stream inclined towards the tank bottom at angle around 25° to 30° . The inclination angle of impeller discharge stream varied in radial direction from impeller as well as with angular position between blades. Flow patterns, mean velocities and normalized turbulence parameters were found unchanged with impeller speed for impeller clearances ($C/T > 0.20$ or $C/T < 0.15$). Therefore, for solid-liquid mixing processes solids can be suspended at lower power with minimum agitator speed. Montante et al. (2001) have tested the capability of CFD model in prediction of flow pattern at various impeller clearances by comparing CFD results with their experimental LDA data (Montante et al.,

1999). The single loop flow pattern was correctly predicted by CFD model. A reasonable agreement between CFD predictions and experimental results was observed for mean flow fields but the angle of impeller discharge stream was overestimated at high clearances. The power number was also well predicted by CFD model and dropped down with lowering impeller clearance. Researchers investigated the details of flow characteristics at $C/T = 0.15$ and a good agreement was found with experimental results. Periodic component of kinetic energy was well predicted, but the random component was underestimated in comparison with experimental results. They tried to improve the CFD predictions with grid refinements and different turbulence models and suggested that further improvements in turbulence model is needed for predictions.

Patil et al. (2004) have experimentally studied the effect of impeller submergence and impeller diameter on mass transfer characteristics in surface aerators. At high impeller submergence the liquid jet stream found deflected towards the liquid surface and this phenomenon resulted in rise of gas-in-liquid dispersion. Subsequently, increase in mass transfer coefficient, bubble entrapment and vortex was observed at the liquid surface. They found the liquid side mass transfer coefficient was high for lower impeller diameter. Deshmukh and Joshi (2006) have reported the similar observations with decreasing power number near gas-liquid interface.

Yapici et al. (2008) have conducted the CFD simulations using LES along with clicking mesh for impeller rotation modelling in Rushton turbine stirred tank. They investigated the effect of design as well as operating parameter on flow hydrodynamics. The design parameters included the impeller off-bottom clearance and the impeller disk thickness, while operating parameter included the Reynolds number based on impeller rotational speed. The mean velocities were well predicted by CFD model when compared to experimental literature data. A smoother circulation flow pattern was observed when impeller was located close to tank bottom. Power number linearly decreased in laminar range while power number was found to be invariant in turbulence regime. They found that the power number decreases with increase in disk thickness.

Ochieng et al. (2008) have carried out the LDV experiments and the CFD simulations at low impeller clearance in Rushton turbine stirred tank and investigated the velocity fields and the mixing time. They observed the transformation of double loop flow pattern to single loop with lowering the impeller clearance and the mixing time was reduced by 35% compared to that of observed standard clearance. Researchers also found that the use of draft tubes at low clearance

enhanced the mixing rate and suppressed the dead zones, and the mixing time reduced by 50%. CFD model over-predicted the mixing time compared to that obtained from experiments. Researchers reported that the reason for over-prediction was $k-\varepsilon$ model which under predicted the turbulence intensity.

Nurtono et al. (2008) have performed CFD simulations using LES and sliding mesh to investigate the effect of impeller clearance on Macro-instabilities. The identification of macro-instabilities occurrence was done by visually observing velocity vectors and time series analysis of both velocity fields in bulk flow and dynamic pressure on the tank wall. They observed the secondary circulation loop and asymmetric flow pattern beside the mean flow pattern.

Rao et al. (2009) have experimentally found that the oxygen transfer rate in both baffled and unbaffled surface aeration tanks increases with the impeller clearance up to the optimum clearance and decreases further. The optimum clearance (C/D) for baffled and unbaffled surface aerators have been reported to be 1.0 and 0.94 respectively. They also found high oxygen transfer rate at lower values of impeller diameter for baffled surface aerators. Continuing this, Rao et al. (2010) have found that the power number was almost constant for $C/H < 1$ and decreased thereafter.

Devi et al. (2011) investigated the effect of impeller clearance on oxygen transfer rate and power consumption at various impeller diameters. They found that at high clearance the power consumption for mixing reduced and increased in oxygen transfer rate. They found the optimal clearance range of 0.7 to 0.9 times the impeller diameter.

Li et al. (2011) have carried out the PIV experiments and large eddy simulations at clearance of $C/T = 0.15$ (low clearance) to investigate the single loop flow field in RT stirred tank. They observed that behind the blades the regions with high level of turbulence kinetic energy were affected by movement of trailing vortices. Two counter-rotating vortices generated behind the blades gradually moved towards the tank bottom with angular rotation when $D = T/3$. They investigated the effect of impeller diameter as well as Reynolds number on flow hydrodynamics. Reynolds number has not significantly affected the mean flow fields and turbulence parameters for configuration of impeller diameter (D) = $T/3$, $C/T = 0.15$. They observed that the single loop flow pattern was gradually transformed into a double loop at $C/T = 0.15$ when impeller diameter (D) was increased from $T/3$ to $T/2$.

Kulkarni and Patwardhan (2014) have investigated the phenomenon of gas entrainment in stirred tank using CFD model. They found that the surface aeration process at gas-liquid interface was characterized by exchange of momentum across the interface from liquid side to air side. The instantaneous axial velocities on air side, strain rates on air side, interfacial momentum exchange and air side vorticities were maximum during the gas entrainment.

Basavarajappa et al. (2015) have performed the steady state CFD simulations for stirred tank agitated by Rushton turbine and floatation impeller. The mean flow fields predicted by Rushton turbine were found in a reasonable agreement with literature LDA data. For Rushton turbine, the mean flow characteristics were invariant with Reynolds number. For floatation impeller, impeller size (D) as well as impeller clearance (C) were varied. Researchers observed the transition of double loop flow pattern to a single loop when impeller clearance was decreased for $D = T/3$. However, no such phenomenon was observed for $D = T/4$ with decreasing impeller clearance. Based on this, they suggested that impeller size and impeller location from tank bottom may affect the critical flow transition clearance. The power number calculated by dissipation rate was severely underestimated by Reynolds stress model.

Chara et al. (2016) investigated the velocity fields in a Rushton turbine stirred tank by using experimental PIV technique and detached eddy simulations (DES) when impeller was located in the mid height of tank. The velocities in impeller vicinity were in a reasonable agreement with the experimental data in radial and axial direction, but tangential velocities were slightly under predicted. Further researchers were able to determine the position and strength of trailing vortices. They concluded that DES is suitable research tool for prediction of turbulence flow fields in a stirred tank agitated by RT.

Zhu et al. (2019) investigated the transition of double loop flow pattern to single loop at low impeller clearance and its effect on macro mixing efficiency using CFD simulations. They found that the critical range of impeller clearance wherein such a flow transition occurred, decreased with increase in impeller diameter and suggested such phenomenon may be easily formed at small Rushton turbines. Researchers observed that at low impeller clearances discharge deflected towards tank bottom, if it hits the tank wall first then the double loop will form, if it hits tank bottom then the single loop will form. They suggested that a single loop flow pattern is helpful to enhance rate of macromixing as the mixing time decreased by 35% at same power input. Further they compared the single loop formed by Rushton turbine and 45° pitched blade turbine. Single loop formed by RT was found less efficient than that of pitched

blade turbine and generally it takes 60% more time to accomplish the same level of macromixing at same power input.

2.4 Scope and Motivation for the Present Study

As observed from various studies reported in the literature (Moslemian et al., 1989; Degaleesan, 1997; Rammohan et al., 2001(a,b) ; Upadhyay, 2010), there are several key factors

such as the tracer particle selection, calibration of the detectors and signal processing which strongly affect the reliability and accuracy in the RPT measurement. Calibration is an important step in RPT wherein radiation intensity emitted by the fixed radioactive tracer particle in the fluid domain needs to be recorded by detectors placed around the stirred tank. No specific data is available in the literature whether the calibration step is to be performed under stationary or moving condition of the fluid inside the stirred tank (Rammohan, 2002; Guha et al., 2007; Bashiri et al., 2016). Thus, it is proposed to address this gap in the present work by conducting the calibration measurement at various known locations in both conditions of fluid motion. The radiation intensity (counts) obtained under both these conditions will be analyzed by Analysis of Variance (ANOVA) statistical method. Further, RPT technique data will be compared with the well-established LDA technique data.

Due to the inherent limitations in the experimental techniques, it is proposed to develop CFD model of stirred tank for investigating the flow hydrodynamics. In the CFD model of stirred tank using MRF technique for modelling of impeller rotation, the dimensions of inner-rotating fluid zone are required to be determined. Though various researchers have used MRF technique (Dong et al., 1994; Ciofalo et al., 1996; Deglon and Meyer, 2006; Ochieng et al., 2008; Basavarajappa et al., 2015), they have not studied the optimality of the dimensions of inner-rotating fluid zone. This gap is addressed in the present work by performing a series of steady state CFD simulations at various dimensions of inner-rotating zone. The optimal dimensions of inner-rotating fluid zone will be determined by comparing the flow characteristics with the experimental literature data. Further, CFD model with optimal inner-rotating fluid zone will be validated with the current RPT work and literature data.

The calibrated and validated CFD model will be used to investigate the effect of geometrical parameters such as impeller clearance and impeller diameter on flow hydrodynamics. The location of impeller has a strong impact on flow hydrodynamics inside the stirred tank (Nienow, 1968; Conti et al., 1981; Montante et al., (1999, 2001); Patil et al., 2004; Deshmukh and Joshi, 2006; Ochieng et al., 2008; Rao et al., (2009, 2010); Li et al., 2011; Devi et al., 2011; Basavarajappa et al., 2015; Zhu et al., 2019). The impeller located near the tank bottom and mid height of tank have been well studied. But the impeller located at the tank top near gas-liquid interface has not been much investigated. While, impeller located at tank top are very useful in various gas-liquid operations to enhance oxygen transfer rate (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et al., 2009; Devi et al., 2011; Kulkarni and Patwardhan, 2014). This gap is addressed in the present work by performing a series of steady state CFD

simulations for impeller located from tank bottom to tank top and their effects on the flow patterns, global flow fields, mean velocity fields and turbulence parameters will be investigated. The impeller diameter is one of the geometrical parameters which affects the flow hydrodynamics. Some of the researches (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et al., (2009, 2010) have investigated the effect of impeller diameter on rate of oxygen transfer and power consumption. But the effect of impeller diameter on flow hydrodynamics (flow fields and turbulence parameters) has not been investigated. This gap is addressed in the present work by performing a series of steady state CFD simulations at various impeller diameters and their effects on power number, mean velocities and turbulence parameters will be investigated.

To accomplish the above mentioned research gaps, in the present work, a standard configured stirred tank equipped with rotating impeller and four equally spaced baffles will be used (Holland and Chapman, 1966; Rammohan et al., 2001 (a,b)). The widely investigated radial type of six bladed disk turbine (Rushton turbine) is selected as stirrer. The rotational speed of impeller will be kept at 200 rpm for RPT experiments as well as CFD simulations. This is the range of impeller speed where fully turbulence flow condition is achieved for standard configured stirred tank and generally used in the various mixing operations (Wu and Patterson, 1989; Rammohan et al., 2002; Montante et al., 1999; Basavarajappa et al., 2015). For current RPT experiments, a radioactive source of Sc-46 emitting γ -radiations will be used. It has been widely used for various RPT studies in the literature (Rammohan et al., 2001; Guha et al., 2007; Bashiri et al., 2016). NaI(Tl) scintillation detectors were used for determination of γ -radiations emitted by radioactive source and these detectors are robust, rugged and relatively inexpensive (Upadhyay, 2010). In CFD modelling of stirred tank, Reynolds Averaged Navier-Stokes (RANS) approach was used to solve transport equations of flow variables. It is computationally less expensive in comparison with large eddy simulation (LES) and direct numerical simulation (DNS) approaches (Murthy et al., 2008; Joshi et al., 2011). A steady state multiple reference frame (MRF) technique was used for modelling of impeller rotation. This technique does not require any experimental boundary conditions and has a capability for reasonable prediction of flow fields at less computational cost (Khopkar et al., 2004; Dewan et al., 2006).

Chapter 3

Materials and Methods

This chapter presents the details of steps involved in the implementation of experimental Radioactive Particle Tracking (RPT) setup for stirred tank, data processing and analysis methods, and CFD methodology used for modelling of stirred tank. It is broadly divided into the following sections:

- 3.1 Experimental Work
- 3.2 Monte-Carlo Algorithm
- 3.3 Analysis of Variance (ANOVA) Technique
- 3.4 CFD Methodology

3.1 Experimental Work

The following experimental aspects have been described in this section:

- The Stirred Vessel Configuration and Experimental Conditions
- The RPT Technique
- The RPT Setup for Stirred Tank
- Preparation of Neutrally Buoyant Tracer Particle
- Calibration of Detectors and Data Acquisition System
- Calibration Measurement in RPT Experiment

3.1.1 The Stirred Vessel Configuration and Experimental Conditions

The standard type of stirred tank was used in the study. It consists of a cylindrical tank with four equally spaced baffles of width $b = T/10$ and six bladed Rushton Turbine (RT) as a stirrer (Figure 3.1). All parts of stirred vessels were made from transparent material (acrylic). Water was used as working fluid. The diameter of the stirred tank (T) is 0.3 m and water is filled up to a height $H = T$. The impeller diameter (D) was kept at $T/3$. The length (l) and width (w) of the blade were kept at $D/4$ and $D/5$ respectively. The thickness of blade and turbine disk was 0.002 m. The impeller was kept at off-bottom clearance (C) of $T/3$. The rotational speed of impeller (N) was 200 rpm. The details of dimensions of stirred vessels and operating conditions are given in Table 3.1.

Figure 3.1 Configuration of stirred tank with Rushton turbine

Table 3.1 Stirred vessel configuration and operating conditions

Tank diameter (T)	0.3 m
Water height in tank (H)	0.3 m
Baffle width (b) = $T/10$	0.03 m
Impeller diameter (D)	0.1 m
Blade width (w) = $D/5$	0.02 m
Blade length (l) = $D/4$	0.025 m
Turbine location from bottom of tank (C) = $T/3$	0.1 m
Density of Water (ρ)	998.2 kg/m ³
Viscosity of Water (μ)	0.001003 Pa.s

3.1.2 The RPT Technique

RPT was used to study the hydrodynamics of water in stirred tank. A γ -ray emitter Sc-46 having strength of 250 μ Ci was used as tracer particle. This particle was chosen for present work, as it is well suited for RPT experiments and same particle was used by Rammohan et al. (2001a) for investigating the flow hydrodynamics in a stirred tank. The path followed by tracer particle was tracked with the help of scintillation detectors placed around the stirred vessel. The particle was designed such that it was neutrally buoyant with the water. During experiments, the tracer particle was allowed to move freely inside the vessel. The position of the tracer particle was determined by an array of scintillation detectors that monitor the γ -rays emitted by the tracer particle. The intensity of radiation recorded at each detector decreases exponentially as the distance between the particle and detector increases and vice-versa. In order to determine the position of the tracer particle from the measured radiation intensities, a calibration step was performed prior to the RPT experiments by placing the tracer particle at various known locations. The data acquired from RPT experiments and calibration measurements was used in Monte-Carlo reconstruction algorithm to determine instantaneous position of tracer particle. The instantaneous velocities were calculated by time differentiation between two successive instantaneous positions. Further, mean velocities were evaluated by time averaging of instantaneous velocities. Following formulae are used for calculation of flow fields.

Instantaneous velocities

$$V_r = \frac{2}{\Delta t} [r_2 \cos(\theta_2 - \theta_1) - r] \quad (3.1)$$

$$V_\theta = \frac{2}{\Delta t} [r_2 \sin(\theta_2 - \theta_1)] \quad (3.2)$$

$$V_z = \frac{\Delta z}{\Delta t} \quad (3.3)$$

$$\text{where, } r = \frac{1}{2} \sqrt{r_1^2 + r_2^2 + 2r_1 r_2 \cos(\theta_1 - \theta_2)} \quad (3.4)$$

Mean velocities

$$\langle v_q(i, j, k) \rangle = \frac{1}{N(i, j, k)} \sum_{n=1}^{N(i, j, k)} v_{q,n}(i, j, k) \quad (3.5)$$

3.1.3 The RPT Setup for Stirred Tank

The RPT set up consists of 8 NaI (TI) scintillation detectors which were strategically mounted on steel supports. Four steel supports were placed around the stirred tank at an angle of 90° to each other. On each support, two detectors were mounted and their faces were kept perpendicular to the tank wall. Figure 3.2(a) depicts the photograph and Figure 3.2(b) depicts the schematic of RPT setup for the stirred tank.

Figure 3.2 Photograph (a) and schematic (b) of RPT setup for stirred tank

The radiations emitted by radioactive tracer particle were sensed by NaI detectors and then processed by data acquisition system. Power was supplied to drive a DC motor which was connected to the rotating shaft of the impeller. With the help of a variable rpm meter, the speed of rotating impeller was controlled. High precision laser Tachometer was used for measuring the speed of rotating shaft.

3.1.4 Preparation of Neutrally Buoyant Tracer Particle

The radioactive tracer particle was made neutrally buoyant in order to mimic the water. In the preparation of neutrally buoyant tracer particle, the plastic ball having 3 mm diameter was taken and it was drilled from one side to make a hole of size slightly greater than 1 mm. After that, the radioactive particle Sc-46 of 1 mm in diameter was inserted into the hole, then the hole was sealed. The density of a neutrally buoyant tracer particle (ρ_p) was measured to be 984 kg/m³. Figure 3.3 shows the schematic (a) and photograph (b) of preparation of neutrally buoyant tracer particle respectively.

Figure 3.3 Schematic (a) and photograph (b) of preparation of neutrally buoyant tracer particle

3.1.5 Calibration of Detectors and Data Acquisition System

Before actually working on RPT experiments, it is important to test the capability of electronics parts for the desired measurement of counts emitted by a radioactive particle. Multi Input Data Acquisition System (MIDAS) unit is an interface between the data received from a detector at one end and provides the data to a computer on the other end. MIDAS unit consists of the following components:

- Power supply
- High voltage (HV) supply
- Amplifier and Single Channel Analyser (SCA) circuit for each detector

The power supply of 5V to 15V was given to provide the high voltage to each individual module. This voltage is then converted to high voltage with the help of Pulse Processing Unit (PPU) provided in MIDAS. High voltage was set at 750 V based on the specifications provided by the manufacturer.

Single Channel Analyser (SCA) is also called as a discriminator and it counts the total number of photons received at detectors between the upper (ULD - upper level discriminator) and lower (LLD - lower level discriminator) threshold. In order to verify the radiation counts measured only from Sc-46 particle, the typical energy spectrum of a source having two energy peaks of 946 KeV and 1.2 MeV were adjusted with the help of oscilloscope as shown in Figure 3.4. In this way, each channel was calibrated to the photon energy of Sc-46 particle.

Figure 3.4 Oscilloscope showing energy peaks for Sc-46 source

Figure 3.5 Testing of detectors to obtain the intensity versus distance map

Initially experiments have been performed for calibration of detectors. In this, a radioactive particle was placed at the center and all eight detectors were placed at equal distance from a particle in a circular fashion. Figure 3.5 depicts the testing of detectors to obtain the intensity-distance count map. The data was acquired simultaneously by all detectors at a single location of particle at frequency of 50Hz (Rammohan et al., 2001(a,b); Guha et al., 2007). Once the measurement was done at a single location of detector, all detectors were moved away from a particle with an increment of 3 cm. The measurements were done at seven different locations of detectors. Figure 3.6 show the radiation counts measured by MIDAS at a fixed location of tracer particle. There are eight channels for eight 8 detectors.

As it is well known in radiation physics, intensity reduces exponentially with the distance between particle and detector. The intensity is a function of the distance between particle and detector, and is expressed using Taylor's expansion of Beer's law:

$$I = f\left(\frac{1}{d}\right) \quad (3.6)$$

where f is a polynomial function of each detector (Devanathan et al., 1990; Degaleesan, 1997). Similar kind of analysis was done for all detectors to verify the capability of detectors. Figure 3.7 shows the plot of radiation intensity versus distance between particle and detector measured by all detectors. It can be seen that all detectors followed the exponential law of radiation intensity.

Figure 3.6 Radiation intensity counts measured by MIDAS software

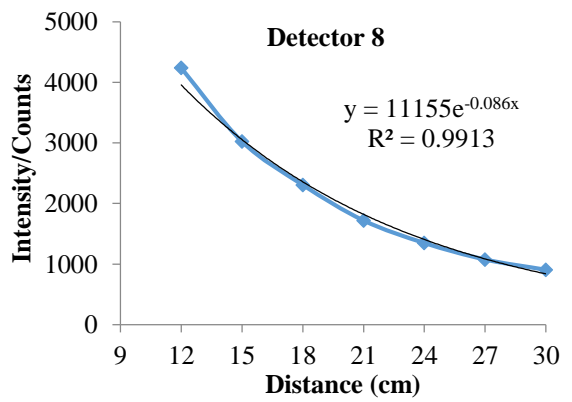

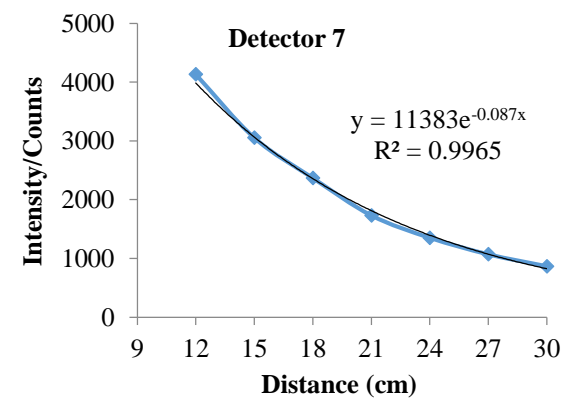

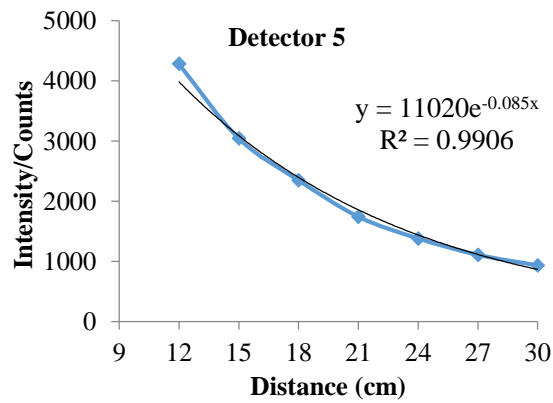

Figure 3.7 Radiation intensity (counts) versus distance plot for Detector 1 to Detector 8

3.1.6 Calibration Step in RPT Experiment

Calibration is the most important step in RPT measurement that needs to be performed prior to actual experiments. In this step, radioactive particle has to be placed at various known locations in a fluid domain and its intensity needs to be recorded by detectors placed outside the stirred tank. In order to conduct the calibration step, a traverse system was developed in such a way that tracer particle can be fixed axially and horizontally at any location in stirred tank. Figure 3.8 depicts the calibration setup developed for stirred tank in which the eight detectors used are represented by notation D_1 to D_8 . Data was acquired at frequency of 50 Hz at every location of tracer particle (500 events/data points).

Figure 3.8 Calibration step in RPT measurement for stirred tank

3.2 Monte-Carlo Algorithm

In present work, the Monte-Carlo algorithm was used to generate the distance-count map for large number of points after calibration measurements for limited points. It is also used to obtain the instantaneous position of tracer particle by linking the calibration measurement data and actual experiment data. This algorithm uses the modelling of emission, transmission and subsequent detection of photons at detectors. In the Monte-Carlo algorithm, photon histories are tracked in their path from source, through the medium and their final detection at detector (Larachi et al., 1994; Beam et al., 1978). In this algorithm, the detector efficiencies in capturing and recording the photons were obtained by considering both the geometry and radiation

effects. The solid angle (angle created by the tracer particle with detector) was accounted to incorporate the geometry effects which considerably affects the detector counting efficiency. The photon peak counts C are calculated by the following equation (Larachi et al., 1994; Roy et al., 2002).

$$C = \frac{T_s \nu A \varepsilon_{abs} \phi}{1 + \tau_d \nu A \varepsilon_{abs} \phi} \quad (3.7)$$

Where, T_s = Sampling time (s)

ν = Number of γ -ray photons emitted per disintegration

A = Source strength (Ci)

ε_{abs} = Absolute efficiency of detector

ϕ = Photo-peak fraction

τ_d = Detector dead time (s)

And the absolute efficiency of detector is given by

$$\varepsilon_{abs} = \oint_{\Omega} \frac{\vec{r} \cdot \vec{n}}{r^3} \exp\left(-\sum_{j=1}^N \mu_j l_j\right) (1 - \exp(-\mu_D d)) d\Sigma \quad (3.8)$$

where \vec{n} = Unit normal vector to the curved surface of the detector

\vec{r} = Radius vector from source to detector

μ_D = The mass attenuation coefficient of the detector crystal material

d = Penetration depth of photons in the detector crystal (m)

μ_j = the mass attenuation of all materials that comes in the path of photons between the source and detector

Source strength, attenuation and dead time for each detector were obtained by the experimental values.

3.3 Analysis of Variance (ANOVA) Technique

ANOVA is the statistical technique which is used to compare the similarity of two or more data sets obtained from the experimental measurements. In present work, it is used to compare the radiation intensities obtained from different rotational speeds of impeller during the calibration

measurement in RPT experiments. The sample of ANOVA analysis is given Table 3.2; however detailed analysis is discussed in next chapter.

Table 3.2 Sample of ANOVA analysis

Source	SS	df	MS	F	$P\text{-value}$	$F_{critical}$
Groups	SSG	$k - 1$	$MSG = \frac{SSG}{k - 1}$	$\frac{MSG}{MSE}$		
Residual	SSE	$n - k$	$MSE = \frac{SSE}{n - k}$			
Total	SST	$n - 1$				

There are two ways for acceptance that the data sets have equal mean. First one is the F , it represents the ratio of variation between data sets to the variation within the data set. Small value of F represents the data sets have equal mean. For equal mean, the value of F should be less than $F_{critical}$. Second one is the $P\text{-value}$, it should be greater than 0.05. It implies that the data sets have equal mean with confidence level of 95% (Rohatgi and Saleh, 2015).

3.4 CFD Methodology

Modelling of a stirred tank using CFD requires knowledge of many aspects of the process. First the domain of interest, in present work it is the volume occupied by the fluid inside the stirred vessel. This entire fluid domain is defined by computational grid, a collection of small sub domains or cells. The flow variables associated with the specific problem are computed in these cells. The computational grid must fit the complex geometry of stirred vessel. Another aspect is the rotation of impeller, it should be modelled in a specific way.

CFD modelling can be done by developing our own code or by using a software. In present work, Ansys Fluent software which is well known for simulating fluid flow problems has been used for CFD modelling of Rushton turbine stirred tank. Fluent is further divided into different parts, starting from creating the geometry, meshing, solution procedure and extraction of simulated data. The various steps involved in CFD modelling have been described in this section; also it is illustrated in the flowchart given (Figure 3.9).

- Design Modeller
- Impeller Rotation Model
- Meshing of CFD Model
- Model Equations and Turbulence Modelling

- Fluent Setup
- Mesh Independent Test
- Turbulence Models Comparison

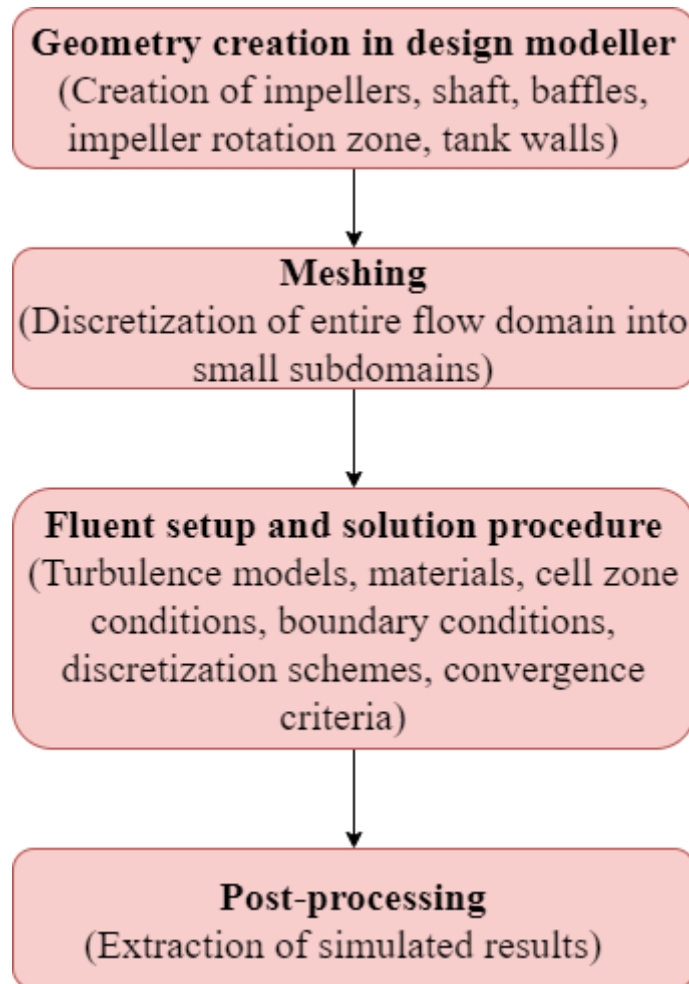

Figure 3.9 Various steps involved in CFD modelling of stirred tank

3.4.1 Design Modeller

The 3D geometry of stirred tank consisting of four equally spaced baffles, impeller mounted on a shaft was created in design modeller. After that, using Boolean operation, the solid bodies such as impeller, shaft and baffles were removed from entire fluid domain. Figure 3.10 shows the 3D geometry of stirred tank for different off bottom impeller clearances.

$C/T = 0.18$ (a)

$C/T = 0.33$ (b)

$C/T = 0.5$ (c)

$C/T = 0.78$ (d)

Figure 3.10 Geometry of stirred tank with different off bottom impeller clearances

3.4.2 Impeller Rotation Model

The impeller rotation was modelled by multiple reference frame (MRF) technique as suggested from literature data (Luo et al., 1994; Deglon and Meyer, 2006). It is a steady state approach. In this approach, tank is divided into two frames, i.e., a moving frame and stationary frame. The moving reference frame encapsulates the impeller and the flow confined by it, the stationary frame includes the baffles and the flow outside moving frame. The impeller is at rest in the rotating frame and the tank walls and baffles are at rest in the stationary frame. The grid

employed for an MRF solution must have a perfect surface of revolution encircling each rotating frame. This inner-rotating zone was created by slicing the fluid zone in the vicinity of the impeller from total fluid domain. Figure 3.10(a) shows the stirred tank with an MRF boundary surrounding the impeller created in the design modeller.

Due to high speed of impeller rotation, the flow variations are very sharp near the impeller. The effective region for sharp variation in flow is 1.5 times of blade height above and below the impeller disc and $D/2$ away from the impeller tip which is reported by Lee and Yianneskis, 1994. Based on this concept, the optimal dimensions of inner-rotating fluid zone (MRF boundaries) were varied radially and axially. The details of MRF boundaries are given section 4.2 (Figure 4.7 and Table 4.8).

3.4.3 Meshing of CFD Model

Generally, the partial differential equations of flow transport are not solved analytically. Therefore, the entire flow domain was divided into smaller subdomains (shapes like hexahedral and tetrahedral in 3D, quadrilaterals and triangles in 2D) to analyse fluid flows. These subdomains are called elements or cells, and the collection of all elements or cells is called a mesh or grid. Further, the discretized forms of flow equations are solved inside the each of these subdomains.

In present work, an unstructured tetrahedral mesh was produced for fluid region, while rotor and baffles have structured hexahedral mesh. Figure 3.11 shows the view of mesh used for flow domain of stirred tank, tetrahedral mesh was used for rotating zone containing impeller, while hexahedral mesh was used for stationary zone containing baffles. Optimization of mesh was done for standard configured stirred tank with six bladed Rushton turbine and four equally spaced baffles and same mesh parameters were kept for further studies. The generated optimized mesh consisted of 3,96,172 elements and 1,95,523 nodes as shown in Figure 3.12. The mesh independence study is discussed in the separate section of this chapter.

3.4.4 Model Equations and Turbulence Modelling

Model Equations

The basic equations used for solution of flow variables in stirred tanks are the mass and momentum conservations equations and these are referred as Navier-Stokes equations. These equations can be written as follows.

Mass Conservation or Continuity Equation

$$\frac{\partial}{\partial x_i}(\rho u_i) = 0 \quad (3.9)$$

Momentum Conservation Equation

$$\frac{\partial(\rho u_i)}{\partial t} + \frac{\partial(\rho u_i u_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left[\mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \frac{\partial u_k}{\partial x_k} \delta_{ij} \right) \right] + \rho \vec{g} + \vec{F} \quad (3.10)$$

Turbulence Modelling

In the turbulence regime, when Reynolds number (N_{Re}) $> 10^3$, fluctuations in the mean velocity and other variables occur. In order to have a better prediction from model, their effects need to be incorporated into the CFD model. Several methods are available to incorporate turbulence in the Navier–Stokes equations. Most of these involve a process of time averaging the conservation equations. In present work, RANS approach is used for modelling of turbulence. In this, the flow variables e.g. velocity, is assumed to be sum of mean and fluctuating

components $(u_i = \bar{u}_i + u'_i)$. After time averaging over many cycles of the fluctuation, terms containing factors of the fluctuating component average to zero. The only term that remains positive definite is one containing the product of two fluctuating terms in momentum equation. The modified equations after using RANS decomposition can be written as follows.

$$\frac{\partial}{\partial x_i}(\rho u_i) = 0 \quad (3.11)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_i u_j) = & -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left[\mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \delta_{ij} \frac{\partial u_k}{\partial x_k} \right) \right] \\ & + \frac{\partial}{\partial x_i}(-\rho \overline{u'_i u'_j}) + \rho \vec{g} + \vec{F} \end{aligned} \quad (3.12)$$

The new term $(-\rho \overline{u'_i u'_j})$ added due to the ensemble averaging in RANS momentum equation is called as Reynolds stresses. These Reynolds stresses need to be modelled appropriately and this can be done using Boussinesq hypothesis. This hypothesis relates the Reynolds stresses to the mean velocity gradients and it can be written as follows:

$$-\rho \overline{u'_i u'_j} = \mu_t \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{2}{3} \left(\rho k + \mu_t \frac{\partial u_k}{\partial x_k} \right) \delta_{ij} \quad (3.13)$$

The new constant, μ_t , is the turbulence or eddy viscosity. Different turbulence models are available to compute the Reynolds stresses. The variants of k - ε turbulence models calculates the μ_t as a function of turbulence kinetic energy (k) and turbulence dissipation rate (ε) with two additional transport equations for k and ε .

In present work, the variants of k - ε turbulence models such as standard k - ε , realizable k - ε and RNG k - ε are tested for prediction of flow fields in a stirred tank. These models have similar forms of transport equation for k and ε , but have some differences are as follows:

- Calculation of turbulence viscosity
- The turbulence Prandtl numbers governing the turbulence diffusion of k and ε
- The generation and destruction terms in the ε equation

Standard k - ε model

It is a robust, economical and has ability to predict the flow in a reasonable accuracy. It is widely used for practical engineering flow calculations, industrial flow and heat transfer simulations. It is based on high Reynolds number. The two transport equations that need to be solved for this model are for the kinetic energy of turbulence, k , and the rate of dissipation of turbulence, ε . The model equations are given as follows:

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j} \left[\left(\mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] + G_k - \rho \varepsilon \quad (3.14)$$

$$\frac{\partial}{\partial t}(\rho \varepsilon) + \frac{\partial}{\partial x_i}(\rho \varepsilon u_i) = \frac{\partial}{\partial x_j} \left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial x_j} \right] + C_{1\varepsilon} \frac{\varepsilon}{k} G_k - C_{2\varepsilon} \rho \frac{\varepsilon^2}{k} \quad (3.15)$$

where G_k represents the rate generation of turbulence kinetic energy due to mean velocity gradients, $C_{1\varepsilon}$ and $C_{2\varepsilon}$ are the model constants, σ_k and σ_ε are the turbulence Prandtl number for k and ε respectively (Pukkella et al., 2019).

The turbulence viscosity is calculated as:

$$\mu_t = \rho C_\mu \frac{k^2}{\varepsilon} \quad (3.16)$$

Realizable k - ε model

The realizable k - ε model (Shih et al., 1995) is addition to the family of two-equation models. It differs from the standard k - ε model in two ways. First, the turbulence viscosity is computed in a different manner, making use of (Equation 3.16) but using a variable for the quantity C_μ . This is motivated by the fact that in the limit of highly strained flow, some of the normal Reynolds stresses, u_i^2 , can become negative in the k - ε formulation, which is unphysical, or unrealizable. The variable form of the constant C_μ is a function of the local strain rate and rotation of the fluid and is designed to prevent unphysical values of the normal stresses from developing. The second difference is that the realizable k - ε model uses different source and sink terms in the transport equation for eddy dissipation. The resulting equation is considerably different from the one used for both the standard and RNG k - ε models.

RNG k - ε model

The RNG k - ε model obtained from statistical technique called renormalization group theory. It is similar to standard k - ε model, but the differences are given as below:

- The additional term in the dissipation rate (ϵ) equation with enhance the predictive capability for rapidly strained flows.
- Addition of effect of swirl flow in turbulence which increases the accuracy of swirling flows.
- Provision of analytic formula for turbulence Prandtl numbers
- The RNG model provides an analytically derived differential formula for effective viscosity that accounts for low Reynolds number effects.

The mean flow fields predicted by variants of k - ϵ models are compared with the literature data and it is provided in the separate section of this chapter.

3.4.5 Fluent Setup

After creation of geometry and mesh, we have to define the setup in Fluent with desirable values. In this section, detail setup for Ansys Fluent with parameters are described.

General

General settings (Figure 3.13) give solver options of pressure, velocity and time. Pressure-based type of solver was used. A steady state simulations were conducted.

Figure 3.13 General setup in Fluent

Models

As explained earlier, RANS based standard k - ϵ turbulence model was used (Figure 3.14). Standard wall function was used to link the viscosity dominated region between the walls and the fully turbulence region (Bashiri et al., 2016).

Figure 3.14 Model setup for $k-\epsilon$ turbulence model

Materials

The water was considered as working fluid. Its properties, density and dynamic viscosity were kept at 998.2 Kg/m^3 and 0.001003 Pa.s respectively (Figure 3.15).

Figure 3.15 Material setup

Cell zone conditions and boundary conditions

Fluid1 represents the inner-rotating fluid zone (MRF boundary) containing impeller and fluid corresponds to the volume outside the inner-rotating zone. The frame motion was enabled for

Fluidi (Figure 3.16). Table 3.3 shows the named selection and boundary conditions used for the present study.

Figure 3.16 Cell zone condition setup

Table 3.3 Boundary conditions

Name	Surface	Boundary Conditions
Tank wall	Tank side and bottom surfaces	Wall
Tank top	Top surface of fluid	Symmetry
Baffle wall	All baffles and their surfaces	Wall
Rotor wall	All surfaces of impeller	Wall
Shaft wall	Cylindrical surface of shaft	Wall

Pressure velocity coupling

In three dimensional simulations, the transport equations include four equations i.e., three for velocity components (momentum) and one for pressure (continuity). Four equations with four unknown, but no explicit equation is available for calculation of pressure. For that Semi-implicit method for pressure linked equation (SIMPLE) algorithm was used to link the velocity and pressure.

In this algorithm, guessed value of pressure is provided in the momentum transport equations. Then compute the new values of velocities, but, in general it does not satisfy the continuity equation and hence corrections to the velocities are determined. From the corrected values of

velocities, correction for pressure is obtained. This corrected pressure value is replaced with original guessed pressure into the momentum transport equations and updated value of pressures is computed. Following the solution of the remaining problem variables, the iteration is complete and the entire process is repeated.

Discretization scheme

In Discretization process, the partial differential form of Navier–Stokes equations converted into algebraic equations and these equations have to be solved by simulation in every cell. It requires an iterative solution procedure, because of the nonlinearity of the flow transport equations. The discretization methods such as finite difference, finite element, spectral element, and finite volume are generally used. In present work, finite volume method based second order upwind scheme was used for discretization of transport equations. Patankar (1980) has given the formulation of finite volume method in scalar equation of following form:

$$\frac{\partial(\rho\phi)}{\partial t} + \frac{\partial}{\partial x_i}(\rho u_i \phi) = \frac{\partial}{\partial x_i}(\Gamma \frac{\partial \phi}{\partial x_i}) + S \quad (3.17)$$

The parameter Γ is used to represent the diffusion coefficient for the scalar ϕ . If ϕ is one of the components of velocity, for example, Γ would represent the viscosity. All sources are collected in the term S . Again, if ϕ is one of the components of velocity, S would be the sum of the pressure gradient, the gravitational force and any other additional forces that are present.

Convergence criteria

Solutions were considered converged when the residuals for continuity, velocity and turbulence quantities reached below 10^{-6} and the field values became almost identical over last 500 iterations. Figure 3.17 shows a typical convergence graph for standard configured stirred tank.

Figure 3.17 Convergence graph

3.4.6 Mesh Independence Test

Mesh independence test was performed at different mesh sizes to obtain the optimum number of cells and to minimize the numerical errors in the results obtained from CFD simulations. Table 3.4 shows the various mesh sizes used in the simulations for standard configured stirred tank. Figures 3.18 and 3.19 show the effect of grid resolution on prediction of power number and normalized profiles of mean radial velocities close to the impeller ($r/R = 1.07$) respectively. Continuous improvements in the prediction of flow fields is observed from Mesh I to III and became identical thereafter. Hence, the grid resolution having 3.9×10^5 elements is adequate for grid independent solutions of flow fields. Hence, the flow field predictions from Mesh III were considered for the further studies investigating the effects of various reactor parameters.

Table 3.4 Details of mesh adopted for CFD model

Mesh	Number of elements	Number of nodes	Power Number (N_p)
Mesh I	104595	115764	4.309
Mesh II	112768	118132	4.511
Mesh III	396172	195523	4.750

Mesh V	2492445	782042	4.829

Figure 3.18 Effect of mesh size on power number

Figure 3.19 Effect of mesh size on normalized profiles of radial velocity at $r/R = 1.07$ and $\theta = 45^\circ$

3.4.7 Turbulence Models Comparison

As mentioned earlier in the turbulence models section, in present work, $k-\varepsilon$ model is used for turbulence modelling. In this section, the comparison of variants $k-\varepsilon$ turbulence model with the experimental literature data is provided to obtain the best model. Figures 3.20-3.22 show the comparison of standard, realizable and RNG $k-\varepsilon$ turbulence models with literature data of Wu and Patterson (1989) for prediction of mean profiles of radial, tangential and axial velocities respectively.

Figure 3.20 Comparison of different turbulence models for prediction of normalized mean radial velocity at different radial distances at angle $\theta = 45^\circ$

Figure 3.21 Comparison of different turbulence models for prediction of normalized mean tangential velocity at different radial distances at angle $\theta = 45^\circ$

Figure 3.22 Comparison of different turbulence models for prediction of normalized mean axial velocity at different radial distances at angle $\theta = 45^\circ$

All turbulence models qualitatively predicted the mean velocities. The peak value of mean radial and tangential velocities near the impeller tip are high and reduces with increase in the radial distance from the impeller. In comparison between the turbulence models, the RNG $k-\varepsilon$ model has given more under/over predictions of mean velocities as compared to the standard and realizable $k-\varepsilon$ models. The radial and tangential velocity predictions from the standard and realizable $k-\varepsilon$ models are highly comparable, while, standard $k-\varepsilon$ model found in a good agreement with the literature data compared to realizable $k-\varepsilon$ model in close comparison. The difference in the CFD results are observed because of assumption of isotropic turbulence condition associated with $k-\varepsilon$ model (Coroneo et al., 2011).

Thus a steady state CFD model was developed for six bladed Rushton turbine stirred tank. Geometry and meshing was created using tool available in Ansys software. The optimum mesh size was found with 3,96,172 number of elements and 1,95,523 number of nodes. The impeller rotation was modelled by MRF technique as suggested from literature data. The standard $k-\varepsilon$ turbulence model has given better predictions compared to other turbulence models. Semi Implicit Method for Pressure Linked Equations (SIMPLE) method was used for coupling of velocity and pressure. Second order upwind scheme was adopted for discretization of transport equations. The convergence criteria were kept at 10^{-6} for continuity, velocity and turbulence quantities. This optimized set of CFD parameters are considered for the further studies investigating the effects of various reactor parameters.

Chapter 4

Results and Discussion

The results obtained from RPT and CFD procedures are discussed in this chapter. It is divided into the following sections.

1. Investigation of Effect of Fluid Motion on Radiation Intensity in RPT Technique, and Comparison of RPT Results with Literature Data

In this study, the effect of fluid motion on radiation intensity during the calibration step in RPT for stirred tank is presented. The comparison of mean counts observed for different rotational speeds of impeller at different locations are investigated by statistical analysis of variance (ANOVA) method. Further, mean velocities obtained from RPT are compared with the literature data.

2. Determination of Optimal Dimensions of Inner-Rotating Fluid Zone for MRF Technique using CFD Model, and Validation of CFD Model with RPT and Literature Data

A series of CFD simulations have been conducted for various dimensions of inner-rotating fluid zone and best optimal zone has been determined by comparing the mean velocities with the literature data. Further, CFD model with optimized inner-rotating fluid zone is validated with current RPT work and literature data.

3. Investigation of Effect of Impeller Clearance on Flow Hydrodynamics in Stirred Tank using CFD Model

In this section, the location of double loop flow pattern transition to single loop at high and low impeller clearance has been investigated. Further, the flow hydrodynamic parameters at low, middle and high impeller clearances have been analyzed.

4. Investigation of Effect of Impeller Diameter on Flow Hydrodynamics in Stirred Tank using CFD Model

In this section, the flow fields at various impeller diameters have been investigated. The flow fields behind the blades at different angles have been studied.

4.1 Investigation of Effect of Fluid Motion on Radiation Intensity in RPT Technique and Comparison of RPT Results with Literature Data

In RPT technique for the stirred tank, the first and most important step is to measure radiation intensity by placing tracer particle at various known locations, known as calibration. In the literature, no data is available whether the calibration step was done under stationary or moving condition of the fluid. With this motive, calibration measurements have been conducted at various locations of tracer particle under both conditions to find the effect of fluid motion on radiation intensity. Fourteen different locations were considered which are represented from L_1 to L_{14} as shown in Figure 4.1. The locations of tracer particle were considered in such a way that these locations are well distributed in the tank volume i.e. very close to the impeller, near baffle, near the tank wall, at the fluid surface and space between tank wall to impeller tip. Once the particle location was fixed, the radiation intensity at that location was measured under stationary and rotating condition of impeller. The impeller was rotated at six different rotational speeds. The details of the calibration measurement conducted at different speeds are given in Table 4.1. Intensity data was acquired at a frequency of 50 Hz at each location of a tracer particle (500 events/data points).

4.1.1 Analysis for Effect of Fluid Motion on Radiation Intensity using ANOVA Technique

ANOVA analysis has been performed for all fourteen locations of tracer particle, however, the detailed ANOVA analysis has been presented at two locations only (details at other locations are available in Appendix). The two locations of tracer particle considered for ANOVA analysis are L_1 (at top of water surface) and L_9 (near to the impeller). The P -value obtained from ANOVA gives the decision of accepting the hypothesis for equal mean of counts. If the P -value is greater than 0.05, it means that the radiation intensity counts measured at different rotational speed have equal mean with a 95% confidence level. Also, F is another factor which shows the variability between group values. If the F is less than $F_{critical}$, it implies that the variability between mean counts is low, i.e. radiation intensity measured at a given location does not change with the velocity of water flowing around the location.

Table 4.2 shows the ANOVA analysis at location 1 (L_1 – near to water surface) for detector 1. It is found that P -value is greater than 0.05 and F is less than $F_{critical}$. It reveals that radiation intensities measured at L_1 for different rotational speeds are independent of motion of fluid in the stirred tank. Figure 4.2 shows the plot of variation in radiation intensity with impeller speed for particle position L_1 and detector 1. It is observed that the mean value of counts at each speed is around 110 which indicates no significant variation in counts. Similar analysis was done for the remaining seven detectors at L_1 . Table 4.3 shows the summary of ANOVA analysis and percentage error between the counts observed at different speeds at L_1 for all eight detectors. It

is observed that at L_I , the criteria for equal mean is satisfied and the maximum percentage error between counts is found to be 0.567 for detector 2 among all detectors.

Table 4.2 Details of ANOVA analysis for detector 1 at L_I

Similar ANOVA analysis has been done at all fourteen locations of tracer particle (L_1 to L_{14}) for all eight detectors. The consolidated summary of ANOVA analysis and percentage error in mean counts under the stationary and moving condition of fluid is shown in Table 4.6. At each location the detector at which the percentage error in mean counts is maximum is shown in Table 4.6.

14	0.311	1.183	2.101	1.070 (at detector 2)

The tracer particle locations $L_6, L_7, L_8, L_9, L_{10}, L_{11}$ and L_{12} are in the vicinity of impeller region where the velocity gradient is sharp. Even at these locations, no change in the counts is observed with the speed of the impeller. Also, the percentage error in the measurement is found to be less than 1.79. The overall analysis shown that the radiation intensity is independent of fluid motion in the entire fluid domain in stirred tank. Hence, the calibration measurement can be done very close to impeller which helps to enhance the accuracy in measurement flow fields close to the impeller. LDA and PIV laser based techniques cannot measure the flow fields accurately within the impeller zone where the flow variation is very high due to the periodic passage of impeller. But, in RPT γ -radiations penetrate the flow and hence the flow variation does not affect the radiation intensity and flow fields can be measured close to the impeller region.

Once it is found that there is no effect of fluid motion on radiation intensity at considered fourteen locations, calibration measurement was done under stationary condition of fluid at 1362 fixed locations of a radioactive tracer particle in a stirred tank to obtain radiation intensity-position values. Then, the Monte-Carlo algorithm was used to generate the position versus

radiation intensity data for the large number of locations in fluid domain. Further, actual RPT experiments were conducted in which radioactive particle was free to move in fluid domain which produced intensity versus time data. The impeller speed was kept 200 rpm and data was acquired at a frequency of 50 Hz. The Monte-Carlo reconstruction algorithm was used to link the data obtained from calibration measurement and actual experiments which resulted in instantaneous position data of tracer particle. Instantaneous velocity data was evaluated by performing the differentiation between two successive instantaneous positions. After that mean velocities were calculated by time averaging the instantaneous velocities.

In the following section, the mean velocities obtained from RPT results are compared with LDA literature data of Wu and Patterson (1989) and LES simulated data of Zadghaffari et al. (2010).

4.1.2 Comparison of Mean Velocities

Figure 4.4 and Figure 4.5 depict the axial profiles of normalized mean radial and tangential velocities respectively at different radial positions from impeller tip. All mean velocity results are plotted along the radial direction in the plane between two baffles. The results obtained from RPT measurements were in a good agreement with the LDA data of Wu and Patterson (1989) and LES simulated data of Zadghaffari et al. (2010). The classical flow pattern for radial impellers, a jet like stream coming from Rushton turbine toward the tank wall is observed from RPT. The peak values of radial and tangential velocities near the impeller tip are high and reduce with increase in the radial distance from the impeller. The distribution of both the velocities is not symmetric at the impeller centre plane where impeller disk is placed, and shift slightly upwards, because the top surface is completely open and the impeller is not placed symmetrically within the vessel (Wu and Patterson, 1989; Bashiri et al., 2016).

The radial velocity profiles at various radial locations from the RPT are close to the LDA measurements while the peak velocities from the RPT are slightly lower (2-13%) than that from the LDA (Figure 4.4). The peak value of radial velocity close to the impeller obtained from RPT technique is much better as compared to the CARPT measurements of Rammohan et al. (2001a) where a relative difference of 34% was found when compared to the LDA measurements of Wu and Patterson (1989). However, the present RPT work has given superior measurement of the peak radial velocity close to the impeller with a relative difference of 5%. This relative deviation may be because of two reasons viz., the difference in the blade thickness and the frequency of data acquisition in LDA (Rammohan et al., 2001a).

Figure 4.4 Axial profiles of normalized mean radial velocity at radial distance of $r/R = 1.07$ (a), 1.29 (b), 1.5 (c) and at angle $\theta = 45^\circ$

Figure 4.5 Axial profiles of normalized mean tangential velocity at radial distance of $r/R = 1.07$ (a), 1.29 (b), 1.5 (c) and at angle $\theta = 45^\circ$

Figure 4.6 Axial profiles of normalized mean axial velocity at radial distance of $r/R = 1.07$ (a), 1.29 (b), 1.5 (c) and at angle $\theta = 45^\circ$

From Figure 4.5, it can be seen that the RPT qualitatively measured the tangential velocity as compared to the LDA measurements. The RPT has given slightly lower values of tangential velocities at the peak locations with a relative difference of 7-10%. However, this measurement is much better in comparison with the earlier CARPT measurements performed by Rammohan et al. (2001a) wherein the respective deviations were 15-25%.

Figure 4.6 depicts the axial profiles of normalized mean axial velocity at different radial positions from impeller tip. RPT accurately measured axial velocities which are almost similar with the LDA measurement. The magnitudes of axial velocity were found to be less than the radial and tangential velocities. Slight differences were observed in the peak values of the RPT in comparison with the LDA.

4.2 Determination of Optimal Dimensions of Inner-Rotating Fluid Zone for MRF Technique using CFD Model, and Validation of CFD Model with RPT and Literature Data

Following the literature, RANS based turbulence model in combination with MRF impeller rotation model is the computationally economic way for CFD modelling of stirred tank. However, the dimensions of inner-rotating fluid zone are required to be determined for MRF technique. Though various researchers have used MRF technique (Dong et al., 1994; Ciofalo et al., 1996; Deglon and Meyer, 2006; Ochieng et al., 2008; Basavarajappa et al., 2015), they have not studied the optimality of the dimensions of inner-rotating fluid zone. With this consideration the issue for the selection of inner-rotating fluid zone, in present work, a series of steady CFD simulations have been conducted to find the optimal dimension of inner-rotating fluid zone by varying diameter and height of zone. In present study, the geometry of stirred tank and operating parameters were considered as reported in the literature data of Wu and Patterson (1989). The details of dimensions used for CFD model of stirred tank are given in Table 4.7.

The dimensions of inner-rotating fluid zones for various CFD simulations are given in Table 4.8 and corresponding diagrammatic representation of inner-rotating zones is shown in Figure 4.7. The optimal inner-rotating fluid zone has been considered where simulation results for velocity predictions such as tangential velocity, radial velocity and axial velocity were found in a reasonable agreement with literature data of Wu and Patterson (1989). Further the

efficiency of CFD model with optimal MRF zone has been validated with the RPT data obtained from present work and literature data.

Table 4.7 Stirred tank dimensions and operating conditions (Wu and Patterson, 1989)

Tank diameter (T)	0.27 m
Water height in tank (H)	0.27 m
Baffle width (b) = $T/10$	0.027 m
Impeller diameter (D)	0.093 m
Blade width (w) = $D/5$	0.0186
Blade length (l) = $D/4$	0.02325 m
Turbine location from bottom of tank (C) = $T/3$	0.093 m
Density of Water (ρ)	998.2 kg/m ³
Viscosity of Water (μ)	0.001003 Pa.s

Table 4.8 Inner-rotating fluid zones and their dimensions

Figure 4.7 Diagrammatic representation of inner-rotating fluid zones

4.2.1 Determination of Optimal Dimensions of Inner-Rotating Fluid Zone

The comparison between CFD predictions and literature data of mean velocities at different inner-rotating zones are depicted in Figures 4.8, 4.9 and 4.10. The mean velocities have been measured at radial distance r/R of 1.07 and $\theta = 45^\circ$. At impeller center plane, the value of radial and tangential velocities reached to maximum, as there is sharp variation in flow fields due to continuous rotation of impeller. CFD slightly under-predicted the normalized radial velocities but qualitatively in a good agreement with literature data. This under-prediction of radial

velocity could be observed because of limitations in $k-\varepsilon$ turbulence model (Basavarajappa et al., 2015). The peak value of mean radial velocity predicted by CFD at zone 6 is in a good agreement with literature data compared to other zones (Figure 4.8). In comparison of tangential velocity, axial location of peak is shifted below as compared with experiments. Also, the trend of tangential velocity observed at zone 6 is in a good agreement with literature data compared to other zones (Figure 4.9).

Figure 4.8 Comparison of mean radial velocity profiles between literature data and CFD predictions for different inner-rotating fluid zones

In order to find the best inner-rotating fluid zone among all seven different inner-rotating fluid zones under consideration, the CFD results of mean radial, mean tangential and mean axial velocities are quantitatively measured in terms of Root Mean Squared Error (RMSE) and correlation coefficient. RMSE and correlation coefficient are the basic statistical indicators commonly used by researchers for quantitative evaluation of model predictions. RMSE measures the difference between the values predicted by the CFD model and the values observed from the literature data. Further, correlation coefficient is estimated which describes

the strength of linear relationship between CFD model predicted values and literature data. The small value of RMSE and the large value of correlation coefficient indicate a good agreement between the CFD predictions and experimental data (Barnston, 1992).

Figure 4.9 Comparison of mean tangential velocity profiles between literature data and CFD predictions for different inner-rotating fluid zones

The dimensions of inner-rotating zones are increased from zone 1 to zone 7 as shown in Table 4.8. Zone 1 is very close to impeller tip and zone 7 is near to baffles. From Figure 4.11, the RMSE in radial velocity decreased from zone 1 to zone 6 and again it increased at zone 7. Similarly, the correlation coefficient for radial velocity increased from zone 1 to zone 6 and decreased at zone 7. The best value of RMSE and correlation coefficient for radial velocity is found at zone 6. Similarly, the best value of RMSE and correlation coefficient for tangential velocity is found at zone 6 as shown in Figure 4.12. But in the case of axial velocity, correlation coefficient and RMSE are good at zone 5 but with very slight difference with zone 6 as shown in Figure 4.13. In present work, Rushton turbine (radial type) impeller is used, wherein radial and tangential components of velocity are the major factor of flow variation compared to axial

velocity. Hence, RMSE and correlation coefficient are considered based on radial and tangential velocities. From the comparison of radial and tangential velocities, CFD results at zone 6 are found qualitatively and quantitatively in a good agreement with the literature data. Hence, zone 6 is considered to be the optimal inner-rotating fluid zone with the radial and axial extent of twice of impeller diameter (D) and 1.5 times of blade height (w) above and below the impeller disk respectively. The predictive capability of CFD model with optimal inner-rotating fluid zone is validated with RPT and literature data. The detailed comparison for mean velocities, re-circulating loops, pumping number, power number and turbulence parameters is discussed in following sections.

Figure 4.12 Correlation coefficient (a) and root mean squared error (b) between CFD predictions and literature data of tangential velocity at different inner-rotating fluid zones

Figure 4.13 Correlation coefficient (a) and root mean squared error (b) between CFD predictions and literature data of axial velocity at different inner-rotating fluid zones

4.2.2 Validation of CFD Model with RPT and Literature Data

4.2.2.1 Prediction of Mean Velocities

Figures 4.14 - 4.16 show the comparison of CFD results with the RPT, LDA literature data of Wu and Patterson (1989) and LES simulated data of Zadghaffari et al. (2010) for radial, tangential and axial velocities at different radial locations respectively. The CFD results are found qualitatively in a good agreement with RPT and literature data. The peak value of radial and tangential velocities near the impeller tip are high and reduces with increase in the radial distance from the impeller. The radial and tangential velocity profiles close to the impeller have shown a good agreement with the respective experimental profiles above and below the impeller centre-plane while some deviations were observed in the peak values of the same. This difference in the peak velocities decreases as the radial distance from the impeller increases. At the normalized radial location of $r/R = 1.5$, a good agreement of peak radial and tangential velocities have been observed. This may be due to the incapability of standard $k-\varepsilon$ model inaccurately predicting the mean velocity fields near the impeller whereas the same provides accurate predictions of the same in the bulk flow region (Basavarajappa et al., 2015). The profiles of mean velocities predicted by current standard $k-\varepsilon$ based simulated results are found to be better in comparison with LES based simulated results of Zadghaffari et al. (2010).

The details of percentage variation between CFD predictions, RPT data and literature data close to the impeller for peak values of mean velocities is given in Table 4.9. The maximum error in the peak mean radial, tangential and axial velocities were found to be 15%, 19% and 27% respectively. The variation in the results for all mean velocities obtained from CFD model at peak points (impeller stream swept region where the velocity gradients are very sharp due to the periodic passage of impeller) may be due to the differences in the blade and disk thickness used for the modelling and that used in the literature (Coroneo et al., 2011).

Table 4.9 Percentage error in the measurements of mean velocities at peak points

Mean velocities	Wu and Patterson (1989) and RPT	Wu and Patterson (1989) and CFD	RPT and CFD	Zadghaffari et al. (2010) and CFD
Radial velocity	5.46 %	15.04 %	10.12 %	3.41%
Tangential velocity	7.09 %	8.33 %	16.61 %	19.39%
Axial velocity	18.30 %	12.79 %	27.57 %	24.56%

Figure 4.15 Comparison of normalized profiles of mean tangential velocity at radial distance of $r/R = 1.07$ (a), 1.29 (b), 1.5 (c) and at angle $\theta = 45^\circ$

Figure 4.16 Comparison of normalized profiles of mean axial velocity at radial distance of $r/R = 1.07$ (a), 1.29 (b), 1.5 (c) and at angle $\theta = 45^\circ$

4.2.2.2 Prediction of Eye of Re-Circulating Loops

The average velocity vector along the mid-baffle plane obtained from the CFD model is shown in the Figure 4.17(a) which adequately illustrates the classic double re-circulation pattern related to the standard configured stirred tank.

Figure 4.17 Velocity vector plot obtained from current CFD work (a) and velocity vector plot of Rammohan et al., 2001b (b)

The impeller stream goes towards the tank walls and it splits into two regions, one of them circulates towards the upper region and other towards the lower region and both finally return to impeller region. The radial and axial locations of the centres or eyes of both the re-circulating loops are accurately predicted by the CFD model when compared to the literature results as given in the Table 4.10.

The impeller discharge stream is mainly radial and characterised by high velocity magnitudes which decrease towards the periphery of the stirred tank. The discharge stream is slightly inclined upwards since the free surface is completely open and the impeller is not placed symmetrically within the vessel (Wu and Patterson, 1989; Bashiri et al., 2016). The higher magnitudes of velocity associated with the lower re-circulation loops make it stronger as compared to upper re-circulation loops and hence the former regions consume more power as compared to the latter regions (Nienow, 1968). Thus, the double re-circulation loops obtained from the present study agree with the literature data of Rammohan et al. (2001b) as shown in Figure 4.17(b).

Table 4.10 Location of eye of re-circulating loops

	Lower (r/T)	Lower (z/T)	Upper (r/T)	Upper (z/T)
Schaeffer et al. (1997)	0.40	0.20	0.40	0.50
Rammohan et al. (2001b)	0.40	0.20	0.40	0.50
Current CFD work	0.39	0.19	0.40	0.51

4.2.2.3 Prediction of Impeller Pumping Capacity

Radial pumping number (N_r) is one of the global flow characteristic which defines the liquid circulation rate in mixing tanks. N_r is obtained by calculating radial impeller pumping capacity (Q_r) and normalized with ND^3 (Equation 4.1). The radial pumping capacity is obtained by integrating the mean radial velocity over the two axial positions at top and bottom edge of impeller tip. Figure 4.18 shows the comparison of CFD predicted radial pumping number with literature data. The radial pumping capacity increases with increase in radial distance from the impeller tip due to the fluid entrainment (Wu and Patterson, 1989).

$$N_r = \frac{Q_r}{ND^3} = \frac{2\pi r \int_{z_1}^{z_2} V_r dz}{ND^3} \quad (4.1)$$

Figure 4.18 Profiles of radial pumping number in the impeller stream

The deviation in pumping number values at most of the radial locations is less than 15%. This shows a good agreement of CFD results with that of experimental results of Wu and Patterson (1989). But the pumping number near the impeller shows large variation from the experimental results and this may be due to the limitations of RANS based $k-\varepsilon$ turbulence model in predicting turbulence quantities (Deglon and Meyer, 2006). Further the thickness of blade and impeller disk are not reported in the literature of Wu and Patterson (1989) which can significantly affect the pumping number predictions (Coroneo et al., 2011). The results of Rushton et al. (1950) show slight deviations from the CFD results as well as results of Wu and Patterson (1989) due to the variation in the impeller geometry, operating conditions and measurement techniques (Wu and Patterson, 1989). CFD predicted radial pumping number is found to be in a good agreement with the LES simulated data of Yapici et al. (2008).

4.2.2.4 Prediction of Power Number

Power required for stirring is the one of the key design factor from process economics point of view. In this study, the effect of Reynolds number on power consumption has been studied. The power consumption is defined in terms of dimensionless power number (Equation 4.2) where P is the power given by impeller to liquid for agitation. The torque (τ) required to calculate the power consumption has been obtained from CFD results.

$$\text{power number } (N_p) = \frac{P}{\rho N^3 D^5} \text{ where } P = 2\pi N \tau, N_{\text{Re}} = \frac{ND^2 \rho}{\mu} \quad (4.2)$$

Figure 4.19 shows the log-log plot of power number versus Reynolds number. In the laminar range ($N_{Re} < 10$), N_p linearly decreases with N_{Re} . In the transitional flow regime ($10 < N_{Re} < 10^4$), slight variation in N_p was observed. In Turbulence regime ($N_{Re} > 10^4$), N_p was observed to be constant with N_{Re} . The CFD predictions of power number in the laminar and transitional regimes shows a good agreement with the experimental results of Rushton et al. (1950) and simulated data of Gillissen and Akker et al. (2012) with the deviation of less than 12%. But the average deviation in the power number predictions between CFD model and experimental results increase to 25% in the turbulence regime. This deviation is partly due to limitations of $k-\varepsilon$ turbulence model and variation in the thickness of blades used in experiments and CFD model (Deglon and Meyer, 2006).

Figure 4.19 Effect of Reynolds number on power number

4.2.2.5 Prediction of Turbulence Parameters

The comparison of axial profiles of normalized turbulence kinetic energy and its dissipation rate with the experimental results of Wu and Patterson (1989) and simulated data of Singh et al. (2011) is shown in Figures 4.20 and 4.21 respectively. The axial profile of turbulence kinetic energy is in a good agreement with the experimental profile as illustrated in Figure 4.20. The double peak curve indicating the trailing vortices near upper and lower edges of the blades were properly predicted. The peak turbulence kinetic energy and its location above the impeller centre-plane were accurately predicted while the same below the impeller centre-plane were over-predicted. The over-prediction of turbulence kinetic energy below the impeller centre-plane may be due to the limitations of standard $k-\varepsilon$ turbulence model as indicated by Deglon

and Meyer (2006) and Coroneo et al. (2011). The results of current CFD model are found much better compared to simulated results of Singh et al., 2011 (RSM model) wherein turbulence kinetic energy has severely under-predicted. Similar under-prediction of turbulence kinetic energy by RSM model has been reported by Murthy and Joshi (2008). The axial profiles of turbulence dissipation rate at normalized radial locations (r/R) of 1.29 and 1.5 are shown in Figures 4.21(a) and 4.21(b) respectively. The axial profiles of turbulence dissipation rate are in a close agreement with the experimental profiles and the locations of peak values are also accurately predicted. However, the turbulence dissipation rate near the impeller centre-plane is under-predicted. The under-prediction of turbulence dissipation rate near the impeller centre-plane may be due to the limitations of standard $k-\varepsilon$ turbulence model and the assumptions involved in the RANS approach (Joshi et al., 2011).

Figure 4.20 Axial profile of normalized turbulence kinetic energy at radial distance of $r/R = 1.07$ and at angle $\theta = 0^\circ$

The under/over prediction of turbulence quantities obtained from this study may be due to the assumption of isotropic turbulence condition associated with the standard $k-\varepsilon$ turbulence model (Joshi et al., 2011). As observed from the comparison of turbulence quantities, Singh et al. (2011) have used completely anisotropic RSM (Reynolds Stress Model) for modelling the turbulence quantities, the respective predictions were also found to be much inferior as compared to the standard $k-\varepsilon$ turbulence model. Therefore, the LES approach may be needed to obtain accurate prediction of turbulence quantities (Montante et al., 2001; Joshi et al., 2011).

But LES approach is computationally more expensive as compared to the RANS approach and hence is unsuitable in the context of practical engineering applications (Khopkar et al., 2004).

Figure 4.21 Axial profiles of normalized turbulence dissipation rate at radial distance of $r/R = 1.29$ (a), 1.5 (b) and at angle $\theta = 0^\circ$

Due to optimal selection of inner-rotating fluid zone in MRF, the CFD model has given a reasonable prediction of mean velocities, double re-circulation loop flow pattern, radial pumping number, power number and turbulence parameters. Hence, CFD model is used for investigation of effect of impeller clearance and impeller diameter on flow hydrodynamics in stirred tank. The detailed investigation is discussed in the following sections.

4.3 Investigation of Effect of Impeller Clearance on Flow Hydrodynamics in Stirred Tank using CFD Model

In stirred tanks, the location of impeller is one of the important geometrical parameters which significantly affect the flow hydrodynamics. The impeller located at bottom and middle of tank have been widely investigated, but impeller located at tank top has not been much investigated. However, many industrial applications such as aeration in wastewater treatment and other gas transfer operations require impeller to be placed near the gas-liquid interface (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et al., 2009; Devi et al., 2011; Kulkarni and Patwardhan, 2014). In standard configured stirred tank, impeller clearance is maintained at $C/T = 0.33$. In the present work, CFD simulations have been conducted from low to high impeller clearances (ranging from $C/T = 0.15$ to 0.85) and its effect on flow hydrodynamics has been investigated.

In this study, the stirred tank geometry and operating conditions were kept same as used for RPT experiments (Figure 3.1) and the impeller clearance (C) was varied. A cylindrical coordinate system was adopted, with r , z and θ indicating the radial, axial and tangential coordinates respectively. Its origin was fixed at center of tank bottom with r , z and $\theta = 0^\circ$, V_r , V_z and $V_{tip} = \pi ND$ represent the mean radial, mean axial and impeller tip velocity respectively.

4.3.1 Validation of CFD Simulation Results at Standard and Low Clearances

In this section, CFD simulation results of flow fields and turbulence parameters at standard and low clearances are compared with literature data. Figure 4.22 shows the comparison of normalized profiles of mean axial velocity with experimental results of Montante et al. (1999) and $k-\varepsilon$ model based simulations of Zhu et al. (2019). The mean axial velocity was calculated for three different clearances ($C/T = 0.33$, 0.2 and 0.15) at axial location of 0.015m below the impeller disk and $\theta = 45^\circ$. A good agreement between CFD simulation results and literature data was observed. At clearance of $C/T = 0.15$, peak points are found to be in good agreement with experimental data, but their locations are slightly shifted. The difference in the prediction may be because of blade and disk thickness which significantly affect the flow fields (Coroneo et al., 2011).

Figure 4.23 depicts the turbulence kinetic energy at $C/T = 0.15$ at various axial locations below the impeller disk and compared with experimental results of Li et al. (2011) and Montante et al. (1999) as well as simulation results of Montante et al. (2001). The profiles are qualitatively in a good agreement with experimental data, but under predictions and shift in peak are

observed. It is reported that the $k-\varepsilon$ model underestimates the turbulence quantities (Montante et al., 2001; Deglon and Meyer, 2006). Although $k-\varepsilon$ model under predicts turbulence kinetic energy, but with the optimal selection of MRF zone, better results can be obtained as shown in Figure 4.23.

Figure 4.22 Normalized profiles of mean axial velocity at impeller center plane for $C/T = 0.33$ (a), $C/T = 0.2$ (b), $C/T = 0.15$ (c) and at $\theta = 45^\circ$

Figure 4.23 Normalized profiles of turbulence kinetic energy at various axial positions for $C/T = 0.15$ and at $\theta = 45^\circ$

4.3.2 Effect of Impeller Clearance on Global Flow Fields and Flow Patterns

Figures 4.24 and 4.25 show the effect of impeller clearance on power number (N_p) and radial pumping number (N_r) respectively. CFD predicted values of N_p and N_r at various impeller clearances are given in Table 4.11 and Table 4.12 respectively. The value of N_p at $C/T = 0.33$ (standard clearance) was found to be 4.82 which is expected for standard configuration and compared with literature data of Bates et al. (1963); Montante et al. (1999) and Coroneo et al. (2011). N_p slightly decreases with lowering the clearance up to $C/T = 0.19$ and it sharply dropped to 3.36 at $C/T = 0.18$ and later it was found to be invariant for further lower clearances. Similarly, with increase in impeller clearance, N_p was found to be invariant up to $C/T = 0.77$ but it suddenly dropped to 3.16 at $C/T = 0.78$ and was constant for further higher clearances. N_p reduces by 30% and 34% at $C/T = 0.18$ and 0.78 respectively in comparison with the standard clearance. The significant reduction of N_p from lower impeller clearance is due to the inhibition of power intensive lower re-circulation loops associated with the standard clearance as the impeller stream is attracted towards the tank bottom (Conti et al., 1981).

The respective changes from double to single re-circulation loop as the impeller clearance reduces from standard conditions to low range is shown in Figure 4.26(a-d). In case of high clearances, the impeller discharge stream is inclined towards top surface and strikes on the top water surface and loses majority of the momentum and thereby producing weaker re-circulation loops below the impeller as displayed in Figure 4.26(e-f). Such type of flow pattern is very useful for exchange of gases from gaseous phase to liquid phase as it helps to increase the surface contact area between gas and liquid (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et al., 2009). Power number is highly dependent on the gas hold-up in the impeller vicinity, at higher clearances the size of this region increases and thus increases the free liquid surface area. Hence it causes the significant reduction in N_p at higher impeller clearances (Deshmukh and Joshi, 2006). Lower clearances develop minor re-circulation loops above the major re-circulation loops which are revolving in the opposite direction to that of major re-circulation loops. Similarly, higher clearances also develop such kind of minor re-circulation loops below the major re-circulation loops as shown in Figure 4.27.

Figure 4.26 Velocity vector plots at various impeller clearances

Figure 4.27 Representation of major and minor re-circulation loops at $C/T = 0.15$ (a) and $C/T = 0.85$ (b)

No considerable variation in the value of N_r was found for medium range clearances, but it suddenly reduced to 0.38 at $C/T = 0.18$ and 0.31 at $C/T = 0.78$ respectively (Figure 4.25). N_r reduced by 44.87% at $C/T = 0.18$ and 55.50% at 0.78 in comparison with the standard clearance. Also, N_r was found to be invariant for $C/T \leq 0.18$ (low clearances) and $C/T \geq 0.78$ (high clearances).

Based on the power number values, the impeller clearances can be divided into three regions i.e. high clearance region ($C/T = 0.78$ to 0.85), middle clearance region ($C/T = 0.19$ to 0.77) and low clearance region ($C/T = 0.18$ to 0.15) for further analysis.

4.3.3 Effect of Impeller Clearance on Mean Velocities and Turbulence Parameters

As mentioned above impeller clearances are divided into three different regions based on the power number values. This section deals with the comparison of normalized mean velocities and turbulence parameters for various impeller clearances. For this purpose, two impeller clearances from each region ($C/T = 0.15, 0.18, 0.33, 0.5, 0.78$ and 0.85) are considered for comparative analysis. Figures 4.28 - 4.31 depict normalized profiles of mean radial velocity, mean axial velocity, turbulence kinetic energy and turbulence dissipation rate respectively at different radial distances from impeller tip.

The middle impeller clearances produce horizontal discharge stream which characterize high magnitudes of mean radial velocity, turbulence kinetic energy and turbulence dissipation rate close to the impeller which reduce as the distance from the impeller increases (Wu and Patterson, 1989). The rate of decay of turbulence dissipation rate from $r/T = 0.18$ to 0.22 (Figure 4.31(a-b)) is much rapid as compared to turbulence kinetic energy and mean radial velocity. The mean radial velocity profile becomes almost constant after $r/T = 0.28$ (Figure 4.28d) while the turbulence quantities continuously decrease with the further increase in the radial distance towards the tank wall. The axial velocity profiles are well developed up to $r/T = 0.28$ (Figure 4.29d) from the impeller and decrease further. The flow fields and turbulence parameters from the middle clearances develop identical patterns with highly comparable peak values and do not show any significant variation. The magnitude of radial velocity, turbulence kinetic energy and turbulence dissipation rate from middle impeller clearances are higher than those from higher and lower impeller clearance indicating better mixing action of the respective configuration.

The higher impeller clearances cause the discharge stream to be deflected towards the water surface and develop re-circulation loops beside the impeller blades. The discharge stream is deflected in such a way that the radial velocity magnitude increases with the radial distance up to $r/T = 0.28$ (Figure 4.28d) and becomes constant thereafter. But the turbulence quantities especially turbulence dissipation rates were much higher near the impeller and reduce with the radial distance from the impeller blades. Again, the higher impeller clearances maintain the sufficient magnitudes of turbulence kinetic energy which is at par with the standard impeller clearance at $r/T > 0.25$. The secondary impeller stream emanating from the trailing edge of the blades generates large undulations in the radial velocity and turbulence kinetic energy up to $r/T = 0.22$ (Figure 4.28b and Figure 4.30b) while the undulations in turbulence dissipation rate extend up to $r/T = 0.28$ (Figure 4.31d). The peak values of radial velocity, turbulence kinetic energy and turbulence dissipation rate at $r/T > 0.18$ occur at the water surface. This leads to high momentum and turbulence action throughout the entire water surface resulting in high interfacial area between water and air. Such phenomenon is extremely suitable for surface aeration process in wastewater treatment plants which leads to superior mixing and transfer of oxygen from atmosphere to the water (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et al., 2009; Kulkarni and Patwardhan, 2014). The axial velocities near the impeller up to $r/T = 0.22$ (Figure 4.29b) are highly comparable with that from middle and low impeller clearances and reduce significantly with further increase in the radial distance.

The low impeller clearances maintain almost constant radial velocity magnitudes till the tank walls while turbulence kinetic energy and turbulence dissipation rate continuously decrease with the radial distance. Significant reduction in the turbulence dissipation rate occurs from $r/T = 0.18$ to 0.22 and continues to decay in a slow rate. The location of peak turbulence kinetic energy lowers axially for $r/T > 0.22$ and remains unchanged thereafter. The turbulence kinetic energy profiles up to $r/T = 0.25$ (Figure 4.30) develop parabolic profile and maintain constant values near the tank bottom (shown by vertical line below the parabolic curve) while usual parabolic profile is observed for $r/T > 0.25$. The fluctuations in the turbulence dissipation rate profiles (Figure 4.31) increase with the radial distance from the impeller and peak magnitudes were obtained at the tank bottom for $r/T > 0.25$. The lower impeller clearances provide significant magnitude of axial velocity even higher than the other impeller clearances up to $r/T = 0.28$ and decreases further. Thus, the impellers located near the tank bottom develop strong axial pumping action and maintain sufficient value of radial velocity and turbulence quantities

(even though low magnitudes) till the tank wall which helps in solid-liquid suspension process in the agitated vessels (Armenante and Nagamine, 1998).

4.4 Investigation of Effect of Impeller Diameter on Flow Hydrodynamics in Stirred Tank using CFD Model

The impeller diameter is one of the geometrical parameters which affects the flow hydrodynamics. Some of the researches (Patil et al., 2004; Deshmukh and Joshi, 2006; Rao et

al., 2009; Rao et al., 2010) have investigated the effect of impeller diameter on rate of oxygen transfer, mass transfer coefficient and power consumption. But the effect of impeller diameter on flow hydrodynamics (flow fields and turbulence parameters) has not been investigated. In present work, impeller diameter (D/T) was varied while keeping other parameters constant. The dimensions of stirred tank and operating conditions were kept same as used for RPT experiments (Figure 3.1). In standard configured stirred tank, impeller diameter is maintained at $D/T = 0.33$ ($D = 0.1$ m, for present geometry). In the present work, CFD simulations have been conducted for impeller diameters ranging from $D/T = 0.2$ to 0.46 . Consequently, Impeller blade width (w) and blade length (l) were maintained at $D/5$ and $D/4$ respectively.

4.4.1 Effect of Impeller Diameter on Power Number and Radial Pumping Number

Power number was calculated using two different methods. In the first method, the power number ($N_{p\tau}$) was calculated by the torque produced on moving parts, viz., impeller blade, disk and shaft (Equation 4.3). In second method, it was calculated by integrating the turbulence dissipation rate through the entire fluid domain (Equation 4.4) and represented by $N_{p\epsilon}$.

$$N_{p\tau} = \frac{2\pi N \tau}{\rho N^3 D^5} \quad (4.3)$$

$$N_{p\epsilon} = \int \frac{\epsilon dV}{N^3 D^5} \quad (4.4)$$

where, N represents the impeller rotational speed, τ is torque on moving parts, ρ is fluid density, D is the impeller diameter, ϵ is the turbulence dissipation rate and V is volume of fluid domain.

Power number increases with increase in the impeller diameter (Figure 4.32), but, the change in the magnitude of power number is small. In comparison between $N_{p\epsilon}$ and $N_{p\tau}$, $N_{p\epsilon}$ is observed to be under-predicted compared to $N_{p\tau}$. The reason for under-prediction of $N_{p\epsilon}$ is k - ϵ turbulence model which predicts the lower values of turbulence dissipation rate (ϵ) (Deglon and Meyer, 2006; Basavarajappa et al., 2015). The overall deviation between $N_{p\tau}$ and $N_{p\epsilon}$ is found to be 15%. Figure 4.33 shows the variation of radial pumping number (N_r) with impeller diameter. It can be observed that N_r increases with increase in the impeller diameter.

Figure 4.32 Effect of impeller diameter on power number

Figure 4.33 Effect of impeller diameter on radial pumping number

4.4.2 Distribution of the Mean Velocities and Turbulence Quantities in r - θ Plane

Figure 4.34 depicts the distribution of mean velocity in r - θ plane located in the mid plane of impeller. The intensity of mean velocity increases with increase in the impeller diameter. The highest peak of velocity is observed at $D/T = 0.46$. The intensity of mean velocity is more near to impeller tip and decrease gradually outside the region swept by the impeller. The baffles on

tank wall reduce the tangential velocity components and avoid the formation of the vortex around the shaft (Ammar et al., 2011).

Figure 4.34 Distribution of mean velocity in r - θ impeller center plane for various impeller diameters

Figure 4.35 depicts the distribution of turbulence kinetic energy in r - θ plane located in the mid plane of impeller. It can be noted that the level of turbulence increases with increase in the

impeller diameter. The turbulence kinetic energy is highly concentrated in the region swept by the impeller and decrease gradually beyond this region. The maximum peak of turbulence kinetic energy is observed at $D/T = 0.46$. The low values of turbulence kinetic energy near the baffles shows that the baffles act as turbulence dissipaters (Ammar et al., 2011).

Figure 4.35 Distribution of turbulence kinetic energy in r - θ impeller center plane for various impeller diameters

4.4.3 Analysis of Flow Hydrodynamics between the Two Impeller Blades at Different Angles

This section deals with the comparison of normalized profiles of mean velocities and turbulence quantities behind the blades at different angles for different impeller diameters. The schematic representation of measurements between two blades at different angles is shown in Figure 4.36.

Figure 4.36 Schematic representation of measurements between two blades at different angles

Figures 4.37 and 4.38 depict the comparison of normalized profiles of mean radial and tangential velocities respectively along with the radial direction located in the impeller center plane at different angles between two blades. The intensity of radial velocity decrease gradually along the radial direction from impeller to tank wall. The peak values of radial velocity decrease from 10° to 30° and again increase from 40° to 50° , because of low velocity regions are formed between two blades (Figure 4.34). The peak values of radial velocity increase with increase in the impeller diameter, and the difference in the peak velocity values for different impeller diameters increase from 10° to 50° . The maximum peak of radial velocity is observed at 50° . The intensity of tangential velocity decrease gradually along the radial direction from impeller to tank wall. The peak values of tangential velocity increase from 10° to 50° . The peak of tangential velocity is observed high at $D/T = 0.2$ in comparison with other impeller diameters.

Figure 4.37 Comparison of normalized profiles of mean radial velocity along the radial direction located in the impeller center plane at different angles between two blades

Figure 4.38 Comparison of normalized profiles of mean tangential velocity along the radial direction located in the impeller center plane at different angles between two blades

Figures 4.39 and 4.40 show the comparison of normalized profiles of turbulence kinetic energy and its dissipation rate respectively along the radial direction at different angles between two blades. The intensity of turbulence kinetic energy and its dissipation rate decrease along the radial direction from impeller. The intensity of turbulence kinetic energy increase with increase in the impeller diameter and its maximum peak is observed at $D/T = 0.46$. The peak value of

turbulence kinetic energy increased from 10° to 40° and it slightly decreased at 50° . The peak values of turbulence dissipation rate are almost constant from 10° to 30° , but significant difference in the peak values are observed for 40° and 50° . The maximum peak of turbulence dissipation rate is observed at impeller diameter of $D/T = 0.46$.

Figure 4.39 Comparison of normalized profiles of turbulence kinetic energy along the radial direction located in the impeller center plane at different angles between two blades

Figure 4.40 Comparison of normalized profiles of turbulence dissipation rate along the radial direction located in the impeller center plane at different angles between two blades

Chapter 5

Conclusions and Future Work

5.1 Conclusions

Experimental and numerical studies have been carried out to investigate flow hydrodynamics in a Rushton turbine stirred tank using RPT technique and steady state CFD model. The following are the conclusions drawn from the study:

Calibration Studies and Comparison of RPT with Literature Data:

- In calibration measurement of RPT technique, radiation intensity measured at a given location does not change with the velocity of water flowing around the measuring point.
- The maximum percentage error in the mean counts obtained from static fluid and moving condition of fluid was observed to be 1.79.
- Axial profiles of mean velocities such as radial, tangential and axial velocities obtained from RPT measurements were found to be in good agreement with literature data.
- Thus with the RPT technique, it is possible to get accurate estimate of velocity fields within the rotor zone which is not possible with other velocity anemometric techniques such as LDA and PIV.

Determination of Optimal Dimensions of Inner-Rotating Fluid Zone for CFD Model, and Validation of CFD Model with RPT and Literature Data:

- The zone with radial extension of twice of impeller diameter (D) and axial extension of 1.5 times of blade width (w) above and below the impeller disk was found to be optimal inner-rotating fluid zone.
- A good agreement between CFD simulations results, RPT results and literature data for mean velocities was observed. But CFD model provided under/over predictions of mean velocities at peak points.
- CFD model accurately predicted the double re-circulation loops flow pattern related to the standard configured stirred tank. The location of eye of upper and lower re-circulation loops were found in a good agreement with literature data.
- CFD model qualitatively predicted the power number and radial pumping number with the overall percentage deviation of 12% and 15% respectively.

- CFD model accurately predicted the turbulence parameters above and below impeller center plane, and the location of peak points. However, under/over predictions were observed at peak points.

Investigation of Effect of Impeller Clearance on Flow Hydrodynamics in Stirred Tank using CFD Model:

- The flow hydrodynamics developed in the stirred tank reactors is well controlled by the location of the impeller.
- The power number and radial pumping number dropped below 30% and 40% when compared to the standard clearance for the impeller clearance range of $C/T \geq 0.78$ and $C/T \leq 0.18$ respectively. The double re-circulation loop flow pattern transformed into a single re-circulation loop, beyond the mentioned clearance range.
- The higher impeller clearance produced high level of momentum transfer as well as turbulence action near the water surface which can enhance the rate of oxygen transfer to the water and it is well suited for the surface aeration process in wastewater treatment plants.
- At the middle impeller clearance, high level of momentum transfer and turbulence action is observed throughout the tank compared to other clearances. Such clearance is much suitable for the applications involving bulk mixing as they produce strong re-circulation loops above and below the impeller, and therefore such clearance can be used for gas-dispersion process.
- The lower impeller clearance provides higher magnitude of axial velocity which is ideal for suspension of solids operation at low power consumption.

Investigation of Effect of Impeller Diameter on Flow Hydrodynamics in Stirred Tank using CFD Model:

- The power number and radial pumping number increased with D/T , however, the change in magnitudes were small.
- The power number predicted by energy dissipation rate (N_{pe}) found to be lower than the power number predicted by torque (N_{pt}). The overall deviation between N_{pt} and N_{pe} is found to be 15%.
- The distribution and intensity of velocity field and turbulence kinetic energy increased with D/T .

- The peak of radial velocities and turbulence quantities observed at $D/T = 0.46$, but, the peak of tangential velocity observed at $D/T = 0.2$.
- The peak of mean velocities and turbulence parameters observed at an angle of 50° behind the blades.

5.2 Future Work

- Simulations may be conducted with the use of unsteady state Large Eddy Simulations (LES) to improve the prediction of turbulence parameters.
- Effect of number and shapes of impellers, degree of baffling may be investigated.

Curriculum Vitae

Name: Patil Harshal Somnath

Gender: Male

Nationality: Indian

Academic Profile:

M.Tech: Chemical Engineering from Vishwakarma Institute of Technology, Pune University, Pune, Maharashtra, India, (2013).

B.E: Chemical Engineering from Pravara Rural Engineering College, Loni, Pune University, Pune, Maharashtra, India, (2011).
